We now estimate the electron super-Coulomb efficiency parameter η which leads to $\gamma_e = 1.352$. For electrons to remain in equilibrium as a result of Coulomb heating and IC cooling over the jet expansion timescale,

$$\frac{(\gamma_e - 1)m_e c^2}{5 \times 10^{-19} n'_e} \cdot \frac{(8.3 \times 10^{-15} T_e'^{3/2} + \beta_p^3)}{\beta_p^2} \cdot \frac{1}{\eta} = \frac{3}{4} \frac{(\gamma_e - 1)m_e c}{U'_\gamma \sigma_T \gamma_e^2 \beta_e^2}, \tag{2}$$

where electron density $n'_e = L/(4\pi R^2 m_p c^3 \Gamma^2) = 4.17 \times 10^{15}$ cm^{-3}, radiation energy density $U'_\gamma = L_\gamma/(4\pi R^2 \Gamma^2 c) = 2 \times 10^{11}$ erg/cm^3 and $T'_e = \frac{1}{k_B}(\gamma_{e,ad} - 1)(\gamma_e - 1)m_e c^2 = 1.98 \times 10^9\,(\gamma_e - 1/\gamma_e)$ is the electron temperature for a Maxwellian distribution. Here, $\gamma_{e,ad} = (4\gamma_e + 1)/(3\gamma_e)$ is the adiabatic index of the electrons and β_p is the speed of protons divided by the speed of light. Substituting $\gamma_p \sim 1.123$ for $\tau_{in} = 8$ and $\gamma_e = \gamma_{e,crit} = 1.352$, we obtain $\eta = 4.5$.[15]

The electrons cannot be continuously heated by Coulomb collisions if the protons cool down to energies comparable to that of electrons within the dynamical timescale. While the protons cool down due to Coulomb collisions and adiabatic expansion, the electrons gain energy through Coulomb and get cooled due to adiabatic cooling and IC. The electrons cannot be heated any further when

$$\begin{aligned} &N_p(\gamma_p - 1)m_p c^2 - N_p \int_0^{t'} \frac{5 \times 10^{-19} n'_e \beta_p^2}{[0.73(\gamma_e - 1/\gamma_e)^{3/2} + \beta_p^3]} \eta dt' - N_p \int_0^{t'} \frac{(\gamma_p - 1)m_p c^2}{R/\Gamma c} dt' \\ &= N_e(\gamma_e - 1)m_e c^2 + N_e \int_0^{t'} \frac{5 \times 10^{-19} n'_e \beta_p^2}{[0.73(\gamma_e - 1/\gamma_e)^{3/2} + \beta_p^3]} \eta dt' \\ &\quad - N_e \int_0^{t'} \frac{(\gamma_e - 1)m_e c^2}{R/\Gamma c} dt' - N_e \int_0^{t'} (4/3) U'_\gamma \sigma_T (\gamma_e^2 - 1) c dt'. \end{aligned} \tag{3}$$

which simplifies for a neutral jet to, $1.5 \times 10^{-3}(1 - \ln\lambda) + 3.21 \times 10^{-5}(1 - 1/\lambda) = 1.15 \times 10^{-4}\eta(1 - 1/\lambda)\tau_{in}$. For $\lambda \sim 2$ i.e. for protons to cool down to electron energies in $t' = 2t'_{dyn}$, $\eta\tau_{in} \sim 8.28$. This means that for $\tau_{in} \gtrsim 10$, the protons cool down too fast and super-Coulomb interaction cannot keep the electrons hot beyond $t' = 2t'_{dyn}$. This necessitates the heating of electrons by some alternate subphotospheric dissipation mechanism. Even though the electrons tend to cool down rapidly due to Comptonization, their energy can still be maintained at $\gamma_e \gtrsim \gamma_{e,crit}$ provided the episodic heating events are frequent enough.

2.2. *Electron heating by repeated dissipation events*

As the total energy gained by the photons is the total energy that is transferred by the electrons through Comptonisation

$$N_\gamma \tau_{in}^{2/3} \left(E'_{\gamma,avg,obs} - E'_{\gamma,avg,i}\right) = N_e \int_0^{\tau_{in} t'_{dyn}} (4/3) U'_\gamma \tau_{in}^{-2/3} \sigma_T \gamma_e^2 \beta_e^2 c\, dt'.$$

which simplifies to

$$10^5\tau_{in}^{2/3}E'_{\gamma,avg,obs} = 8.72\times10^6 L_{\gamma,50}\tau_{in}^{-2/3}\int_{R_{in}}^{\tau_{in}R_{in}}(\gamma_e^2-1)\frac{dR}{R^2}$$
$$\sim \frac{8.72\times10^6 L_{\gamma,50}\tau_{in}^{-2/3}(\gamma_e^2-1)}{R_{in}}.$$

Substituting $R_{in}\sim 2.17\times10^{11}\ \tau_{in}^{-1}$ cm, yields $\gamma_{e,crit}\sim\sqrt{1+1.2\ L_{\gamma,50}^{-1}\ \tau_{in}^{1/3}}$. The critical electron energy obtained here is similar to $\gamma_{e,crit}\sim 1.352$ obtained earlier, especially for small initial optical depths $\tau_{in}\sim 1$.

We consider repeated sub-photospheric dissipation events that can re-accelerate the electrons as well as protons to their initial energies.

Using the fact that the electrons remain in equilibrium with energy $\gamma_{e,\rm crit}\sim\sqrt{1+1.2\ L_{\gamma,50}^{-1}\ \tau_{\rm n}^{1/3}}$, we constrain the energy injected per electron $E_{inj}=N_{rh}(\gamma_{e,in}-1)m_ec^2$. In particular,

$$N_e\tau_{in}^{4/3}(\gamma_e-1)m_ec^2 = N_e\int_0^{\tau_{in}t'_{dyn}}\frac{5\times10^{-19}n'_e\beta_p^2\tau_{in}^{-4/3}}{[0.73(\gamma_e-1/\gamma_e)^{3/2}+\beta_p^3]}dt'$$
$$+N_eN_{rh}(\gamma_{e,in}-1)m_ec^2 - N_e\int_0^{\tau_{in}t'_{dyn}}(4/3)U'_\gamma\tau_{in}^{-2/3}\sigma_T\gamma_e^2\beta_e^2c\ dt', \qquad (4)$$

where $\gamma_e\approx\gamma_{e,crit}$ and $\tau_{in}^{-4/3}/\tau_{in}^{-2/3}$ is the adiabatic cooling factor for relativistic electrons/photons. We consider the episodic dissipation events to be equally spaced over the jet expansion timescale $\tau_{in}t'_{dyn}$ and to supply fixed energy (equal to initial energy, $\gamma_{e,in}/\gamma_{p,in}$) to the electrons/protons at each instance. Substituting $R_{\rm in}=2.17\times10^{11}\ \tau_{\rm in}^{-1}$ cm and simplifying yields

$$\tau_{in}^{4/3}(\gamma_e-1)m_ec^2 = \frac{10^{-4}\tau_{in}^{-4/3}}{[0.73(\gamma_e-1/\gamma_e)^{3/2}+(2/\tau_{in})^{3/2}]}+E_{\rm inj,cr}-3.21\times10^{-5}\tau_{in}^{-2/3}, \qquad (5)$$

which constrains the critical injected energy $E_{inj,cr}(\tau_{in})=N_{rh}(\gamma_{e,in}-1)m_ec^2$ per electron in terms of τ_{in}. Equation (5) is only a necessary and not sufficient condition to obtain Band-like photon spectrum as it determines the average photon energy but does not impose any constraints on the general shape of the photon spectrum. For large E_{inj}, photon peak energy $E_{\gamma,peak}\gg E_{\gamma,obs}\sim 300$ keV while $E_{\gamma,peak}\ll E_{\gamma,obs}$ for large τ_{in}, due to significant energy loss from adiabatic cooling.

3. MCRaT code description

We discuss here the implementation of our MCRaT code and give an overview of the basic physics included. We first list the jet parameters and describe the initial distributions of the particles and the photons. We then discuss how the jet particles and photons are affected by the physical processes. Lastly, we describe the algorithm of our photospheric MCRaT code.

3.1. *Relativistic jet parameters*

The jet parameters provided as input for the code are:

- *Isotropic equivalent luminosity, L*: The bulk of the jet luminosity is contributed by the protons. We consider $L = 10^{51}, 10^{52}$ erg/s.[20]
- *Jet bulk Lorentz factor,* Γ: The bulk Lorentz factor is related to L and $E_{\gamma,peak}$. We consider $\Gamma = 30, 100, 300$ in this work.[21]
- *Initial optical depth,* $\tau_{\rm in}$: The optical depth is measured relative to $R = L\sigma_T/(8\pi m_p c^3 \beta \Gamma^3 \tau)$ which is the photon radial distance from central engine in the observer frame. $\tau_{\rm in}$ corresponds to the radial distance from central engine where all particles and photons are injected. We consider $\tau_{\rm in} = 10, 20, 40$.

3.2. *Initial distributions*

We describe here the initial energy and velocity distributions of the jet electrons, protons and photons.

- *Electrons and protons:* We consider a charge-neutral jet with particle number $N_e = N_p = 2 \times 10^2$. The initial particle velocities are distributed randomly in the jet-comoving frame. All particles are uniformly distributed in the jet-comoving frame at initial time. The initial energy of the electrons are determined from the Maxwellian distribution with temperature $k_B T'_{e,in} = (\gamma_{e,ad,in} - 1)(\gamma_{e,in} - 1) m_e c^2$ while the protons are mono-energetic with $\gamma_p = \gamma_{p,in}$. We consider $\gamma_{e,in} = 2, 10, 30, 100$ and $\gamma_{p,in} = 1.01, 1.1$ for our simulations.
- *Photons:* In order to maintain $N_\gamma/N_e = 10^5$, we consider $N_\gamma = 2 \times 10^7$ for our simulations.[15] The initial photon velocities are randomly distributed in the jet-comoving frame and photon positions are uniformly distributed within a cone of solid angle $1/\Gamma$ pointing towards the observer. The initial photon energy distribution is given by the synchrotron distribution for fast cooling electrons[5]

$$f_\nu = \begin{cases} \left(\frac{\nu_{ac}}{\nu_{sa}}\right)^{11/8} \left(\frac{\nu}{\nu_{ac}}\right)^2, & \nu_{min} < \nu < \nu_{ac} \\ \left(\frac{\nu}{\nu_{sa}}\right)^{11/8}, & \nu_{ac} < \nu < \nu_{sa} \\ \left(\frac{\nu}{\nu_{sa}}\right)^{-1/2}, & \nu_{sa} < \nu < \nu_m \\ \left(\frac{\nu_m}{\nu_{sa}}\right)^{-1/2} \left(\frac{\nu}{\nu_m}\right)^{-p/2}, & \nu_m < \nu < \nu_{max} \end{cases} \tag{6}$$

  where f_ν is the peak normalised photon flux per unit frequency and $p = 2.5$ is the spectral index at high energies.[6]

3.3. *Physical processes in the jet*

Here we discuss the physical interactions between the electrons, protons and photons that can further affect the output photon spectrum.

- *Adiabatic cooling:* As the relativistic jet expands outward, the photon and particle energies drop considerably as

$$(\gamma_{e,f}-1)/(\gamma_{e,i}-1) = \left(R_{\rm in}+\beta c\Gamma t'_f/R_{\rm in}+\beta c\Gamma t'_i\right)^{-2(\gamma_{\rm ad,e}-1)},$$
$$(\gamma_{p,f}-1)/(\gamma_{p,i}-1) = \left(R_{\rm in}+\beta c\Gamma t'_f/R_{\rm in}+\beta c\Gamma t'_i\right)^{-2(\gamma_{\rm ad,p}-1)},$$
$$E_{\gamma,f}/E_{\gamma,i} = \left(R_{\rm in}+\beta c\Gamma t'_f/R_{\rm in}+\beta c\Gamma t'_i\right)^{-2/3}, \quad (7)$$

  where the subscript i/f denotes the initial/final value of the physical quantity and $\gamma_{ad,e/p} = (4\gamma_{e/p}+1)/(3\gamma_{e/p})$ is the electron/proton adiabatic index.
- *Coulomb collisions:* While the electrons are continuously heated by the protons in the jet, they also interact with each other to quickly attain thermal equilibrium. The corresponding timescales are given by[22]

$$\dot{E}_{e-p} = \frac{5\times10^{-19}n'_e\beta^2_{\rm p,avg}}{8.3\times10^{-15}T'^{3/2}_{\rm e,avg}+\beta^3_{\rm p,avg}},$$
$$\dot{E}_{e-e} = \frac{5\times10^{-19}n'_e\beta^2_{\rm e,avg}}{8.3\times10^{-15}T'^{3/2}_{\rm e,avg}+\beta^3_{\rm e,avg}}, \quad (8)$$

  where $\beta_{p,avg}$, $\beta_{e,avg}$ and $T'_{e,avg}$ are number-averaged quantities. The electron distribution is re-initialized to Maxwellian distribution on a timescale $t'_{e-e} = (\gamma_{e,avg}-1)m_ec^2/\dot{E}_{e-e} \ll t'_{e-p}$.
- *IC scattering:* The distance s' that a photon travels before scattering an electron is given by probability density $p(s') \propto \exp(-s'/l'_{\rm mfp})$, where $l'_{\rm mfp} = 1/(n'_e\sigma_T)$ is the photon mean free path. The scattering probability of a particular electron with a photon is[15]

$$P_{sc}(\beta_e,\theta'_e) = \frac{1}{4\pi\beta_e^2}(1-\beta_e\cos\,\theta'_e), \quad (9)$$

  where β_e is the electron speed divided by speed of light and θ'_e is the angle between electron and photon velocities before scattering. Average number of scatterings that a photon experiences before escaping is $\sim 2\tau_{in}$.[23]
- *Pair production/annihilation:* Due to the episodic jet dissipation events, the electrons are often accelerated to highly relativistic energies $\gamma_e = \gamma_{e,in} \sim 100$ and can scatter energetic photons with $E'_\gamma \gtrsim 10\ E'_{\gamma,peak}$ to energies $\gtrsim 4E'_{\gamma,avg}\gamma_e^2 \sim m_ec^2 \sim 5\times10^5$ eV, before cooling down rapidly to non-relativistic energies. For synchrotron photons that we consider (see equation 6), a considerable fraction $\sim 30\%$ have sufficient energy to generate electron-positron pairs which can affect the shape of the output photon spectrum, especially for large $\tau_{in} \gtrsim 10$.

3.4. *Code implementation*

The travel distances are first drawn for all photons depending on their mean free path and the photons are propagated. The new photon positions are evaluated to check if any photon escapes the photosphere, in which case the energy is calculated

and stored. Other photons are stored in a priority queue where they are ordered based on travel distances. Next, the photon at the top of the queue is propagated, a proton is randomly selected and an electron is selected using the scattering probability, P_{sc}. The particle and photon energies are then updated due to adiabatic cooling and Coulomb collisions. The outgoing velocities and energies of the photon and electron are calculated if IC scattering occurs. Subsequently, the next photon in the queue is drawn and electron-positron pair production cross section is evaluated. If the cross section is large, a new electron and positron are generated and photons are not placed back in the queue. If positron number is non-zero, a positron is drawn randomly and the pair annihilation cross section with the electron is calculated. Two new photons are created and added to the queue, if the cross section is significant. The method described above is repeated until a third of the total photons in the jet escape and a time-averaged output photon spectrum is obtained.

4. Photospheric simulation results

Here we present the results of our photospheric MCRaT simulations. The photon energy spectrum and the electron kinetic energy spectrum are shown in the lab frame at the end of each simulation in all the figures. The photon and electron energy spectrum are Doppler boosted from the jet-comoving frame to the lab frame in all the figures. The electron kinetic energy spectra are peaked at significantly larger energies compared to the photon spectra for all the simulations as shown in the figures. In the rest of this paper, we denote the low/high energy photon spectral index by α/β and the observed photon peak energy by $E_{\gamma,obs}$.

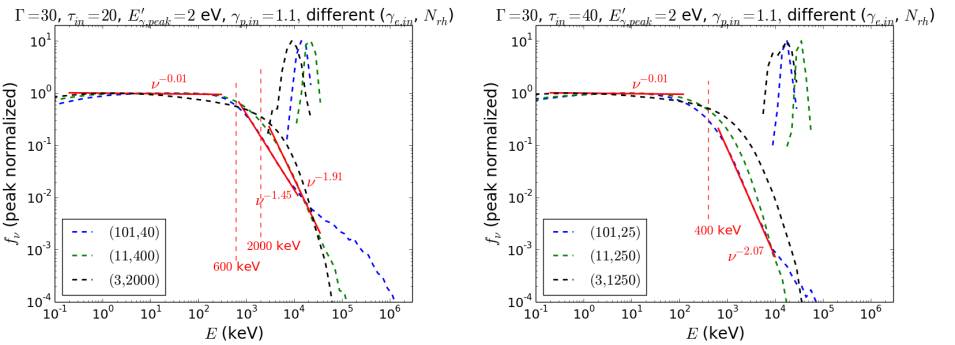

Fig. 1. **Effect of $\gamma_{e,\rm in}$ at constant $E_{\rm inj} = E_{\rm inj,cr}(\tau_{\rm in})$ and for different $\tau_{\rm in}$.** The input parameters used are $E'_{\gamma,\rm peak} = 2$ eV, $\gamma_{p,\rm in} = 1.1$, $L = 10^{52}$ erg/s and $\Gamma = 30$. *Left panel:* $\tau_{\rm in} = 20$, $E_{\rm inj} = 4000\ m_e c^2$ and $(N_{\rm rh}, \gamma_{e,\rm in}) = (40, 101)/(400, 11)/(2000, 3)$. *Right panel:* $\tau_{\rm in} = 40$, $E_{\rm inj} = 2500\ m_e c^2$ and $(N_{\rm rh}, \gamma_{e,\rm in}) = (25, 101)/(250, 11)/(1250, 3)$.

In Figure 1, we present the simulation results for fixed injected energy $E_{\rm inj,cr} = N_{\rm rh,cr}(\gamma_{e,in} - 1)\ m_e c^2 = 4000/2500\ {\rm m_e c^2}$ at $\tau_{in} = 20/40$ and different $\gamma_{e,in} = 3, 11, 101$. The photons/protons are initialized with $E'_{\gamma,peak} = 2$ eV/$\gamma_{p,in} = 1.1$

with jet parameters, $L = 10^{52}$ erg/s and $\Gamma = 30$. We find that $\alpha \sim 0$ is practically unaffected by decrease in electron energy $\gamma_{e,in}$ (irrespective of τ_{in}) and is solely determined by the critical injected energy $E_{inj,cr}$. As $\gamma_{e,in}$ increases for a given $E_{inj,cr}$, the photons tend to have lower peak energy $E_{\gamma,peak}$ and there are fewer/more photons with $E_\gamma \sim 1-10$ MeV/$\gtrsim 100$ MeV. This is expected as the electrons with $\gamma_{e,in} = 101$ are accelerated much less frequently compared to those with $\gamma_{e,in} \sim 3-11$ and then subsequently cool down very rapidly to non-relativistic γ_e after being considerably hotter for a shorter duration $\sim 10^{-3}\ t_{dyn}$ when they accelerate many photons to $E_\gamma \gtrsim 100$ MeV. The high energy bump in f_ν and deviation from power-law behaviour for large $\gamma_{e,in}$ is seen only at moderate $\tau_{in} \lesssim 20$ and is not appreciable for larger $\tau_{in} \gtrsim 40$ as the high energy photons cool down rapidly from adiabatic losses.

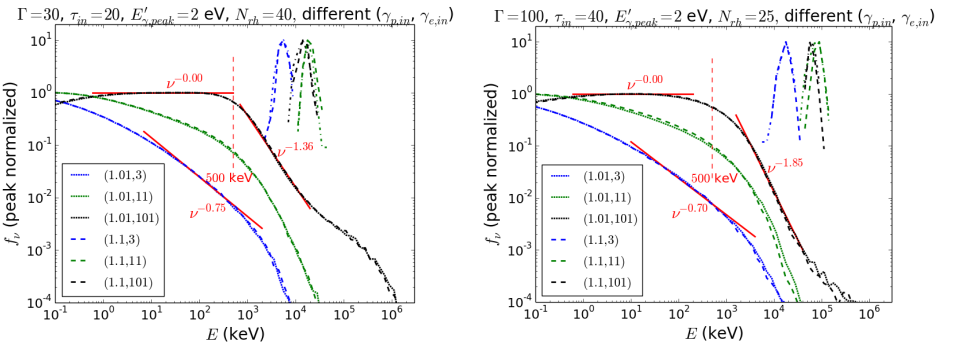

Fig. 2. **Effect of $\gamma_{p,in}$ and $\gamma_{e,in}$ for $N_{rh} = 40$ ($\tau_{in} = 20, \Gamma = 30$) and $N_{rh} = 25$ ($\tau_{in} = 40, \Gamma = 100$).** The input parameters used are $E'_{\gamma,peak} = 2$ eV and $L = 10^{51}$ erg/s. *Left panel:* $\Gamma = 30$, $\tau_{in} = 20$, $N_{rh} = 40$: $\gamma_{p,in} = (1.01, 1.1)$ and $\gamma_{e,in} = (3, 11, 101)$. *Right panel:* $\Gamma = 100$, $\tau_{in} = 40$, $N_{rh} = 25$: $\gamma_{p,in} = (1.01, 1.1)$ and $\gamma_{e,in} = (3, 11, 101)$.

We find an increase in $|\beta|$ with decrease in $\gamma_{e,in}$ for a fixed $E_{inj,cr}(\tau_{in})$ as well as with increase in τ_{in}. Moreover, $\beta \sim \beta_{obs}$ for $\gamma_{e,in} \sim$ few 10s $-$ 100 and $\tau_{in} \lesssim 20$ while the high-energy spectrum is much steeper, $f_\nu \propto \nu^{-2}$ for $\tau_{in} \gtrsim 40$, almost independent of N_{rh}. While relatively continuous energy injection (small $\gamma_{e,in} \sim$ few and large $N_{rh,cr} \sim$ few 1000s) results in steeper high energy spectra $|\beta| > |\beta_{obs}|$ along with $E_{\gamma,peak}/E_{\gamma,obs} \gtrsim 10$, episodic energy injection (large $\gamma_{e,in} \sim 100$ and small $N_{rh,cr} \sim$ few 10s) gives a high energy power-law spectrum consistent with observations for moderate optical depths $\tau_{in} \lesssim 20$. In order to have both $E_{\gamma,peak} \sim 500$ keV and $|\beta| \sim 1.2-1.5$, the particles and photons have to be initialized at $\tau_{in} \sim 20-40$ and $E_{inj,cr}(\tau_{in}) \sim 2500-4000\ m_e c^2$ energy needs to be injected into electrons with $\gamma_{e,in} \sim$ few 10s.

In Figure 2, we present the simulation results for fixed $N_{\rm rh,cr}(\tau_{\rm in}) = 40/25$ at $\tau_{\rm in} = 20$ ($\Gamma = 30$)/40 ($\Gamma = 100$) with different combinations of $\gamma_{e,\rm in} = 3, 11, 101$ and $\gamma_{p,\rm in} = 1.01, 1.1$. The seed photons have energy $E'_{\gamma,\rm peak} = 2$ eV with jet luminosity

$L = 10^{51}$ erg/s. We see that $\gamma_{p,\rm in}$ does not affect the photon output spectra irrespective of the optical depth, which is expected as the Coulomb collisions timescale $t'_{e-p} = (\gamma_{e,avg} - 1)m_e c^2/\dot{E}_{e-p}$ is considerably longer than the Comptonization timescale t'_{IC}. A minimum electron energy $\gamma_e \gtrsim 11$ is needed in order to have photons with $E_\gamma \gtrsim 10$ MeV and peak energy $E_{\gamma,peak} \sim 1$ MeV for both τ_{in} considered. The output photon spectrum does not show a power-law dependence at both low and high energies when the electron initial energy is small $\gamma_{e,in} \lesssim 11$. While the output photon spectrum shows $\alpha \sim \alpha_{obs}$ and $E_{\gamma,peak} \sim E_{\gamma,obs}$ at both optical depths for electrons with $\gamma_{e,in} = 101$ only, the high energy power-law spectral index $|\beta| \gg |\beta_{obs}|$ for $\tau_{in} = 40$ and $\sim |\beta_{obs}|$ for $\tau_{in} = 20$.

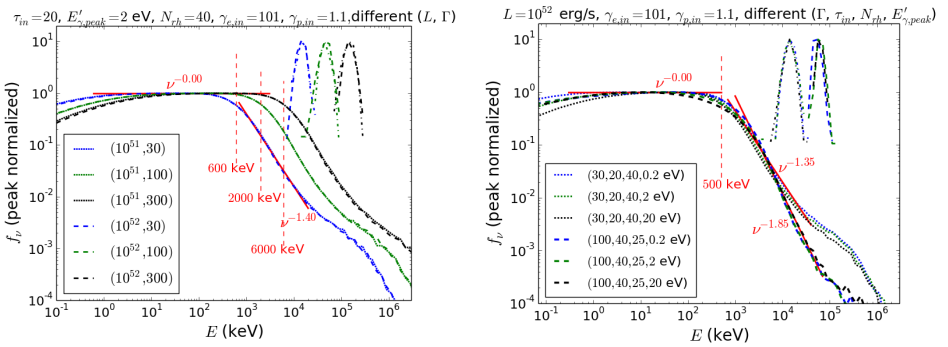

Fig. 3. *Left panel:* MCRaT simulations showing the effect of $L = (10^{51}, 10^{52})$ erg/s and $\Gamma = 30, 100, 300$ for constant $N_{rh} = 40$, $\gamma_{e,in} = 101$ and $\tau_{in} = 20$. For these simulations, we consider input parameters $E'_{\gamma,peak} = 2$ eV and $\gamma_{p,in} = 1.1$. *Right panel:* MCRaT simulations showing the effect of $E'_{\gamma,peak} = 0.2, 2, 20$ eV for $N_{rh} = 40$ ($\tau_{in} = 20, \Gamma = 30$) and $N_{rh} = 25$ ($\tau_{in} = 40, \Gamma = 100$). For these simulations, we consider input parameters $\gamma_{e,in} = 101$, $\gamma_{p,in} = 1.1$ and $L = 10^{52}$ erg/s.

In the left panel of Figure 3, we show the simulation results for fixed $E_{\rm inj,cr} = 4000\ m_e c^2$ at $\tau_{in} = 20$ and for different combinations of $L = 10^{51}, 10^{52}$ erg/s and $\Gamma = 30, 100, 300$. The photons/electrons/protons are initialized with energies $E'_{\gamma,peak} = 2$ eV/$\gamma_{e,in} = 101/\gamma_{p,in} = 1.1$ at optical depth $\tau_{in} = 20$. While the jet luminosity L has no noticeable effect on the output photon spectrum, increase in bulk Lorentz factor Γ shifts the photon peak energy to higher values. We find that even though Γ does not affect α and β, it rescales photon peak energy as $E_{\gamma,peak} \propto \Gamma$. The output photon spectrum shows $E_{\gamma,peak} \sim E_{\gamma,obs}$ only for smaller $\Gamma \sim 30$ values. While larger $\Gamma \sim 100$ can also reproduce $E_{\gamma,peak} \sim 500$ keV and $\alpha \sim 0$ at $\tau_{in} \gtrsim 40$ in agreement with the observations, it cannot explain the observed high energy spectral index (see right panel of Figure 2).

In the right panel of Figure 3, we show the simulation results for fixed $N_{rh,cr}(\tau_{in}) = 40/25$ at $\tau_{in} = 20$ ($\Gamma = 30$)/40 ($\Gamma = 100$) and different seed photon energies $E'_{\gamma,peak} = 0.2, 2, 20$ eV. The electrons/protons are initialized with energies $\gamma_{e,in} = 101/\gamma_{p,in} = 1.1$ with jet luminosity $L = 10^{52}$ erg/s. We find that for

both $E_{inj,cr}(\tau_{in}) = 2500\ m_e c^2$ and $4000\ m_e c^2$, the low/high energy spectral index α/β and the output photon peak energy $E_{\gamma,peak}$ are practically unaffected by the choice of $E'_{\gamma,peak}$. The specific photon flux f_ν falls off considerably at energies less than $\Gamma E'_{\gamma,peak}$ as most of the photons gain energy and do not populate the low energy tail after getting scattered by the electrons. For larger τ_{in}, the photons get scattered multiple times thereby increasing the probability of differential number of scatterings before escaping the photosphere and subsequent broadening of the spectrum. As a result, more photons populate the low energy tail and the spectra with different initial energies $\Gamma E'_{\gamma,peak}$ become indistinguishable for $\tau_{in} \gtrsim 40$.

5. Photon spectra for repeated scatterings

Assuming that Comptonization is the dominant process influencing the output photon spectrum, we will first evaluate the energy spectrum of synchrotron photons after they experience single scattering with the electrons. Then we extend our formalism to find the photon energy spectrum for the realistic case when they undergo repeated scatterings with the electrons in the jet before exiting the photosphere. The energy distribution of the scattered photons depends mainly on the incident photon spectrum and the electron energy distribution.

5.1. *Photon distribution after one scattering*

For our calculation, we consider electrons and incident photons with isotropic distributions in the jet-comoving frame. In this case, the scattered photons are also distributed isotropically in the jet-comoving frame. For simplicity, we only consider Thomson scattering in the rest frame of the electron and assume that all scattering events are elastic in nature. For incident photons with energy ϵ scattering off electrons with energy $\gamma m_e c^2$, the total scattered power per energy per volume is[24]

$$\frac{dE}{dV dt d\epsilon_1} = \frac{3}{4} c\sigma_T \int_{\epsilon_1/4\gamma^2}^{\infty} d\epsilon \frac{\epsilon_1}{\epsilon^2} f(\epsilon) \int_1^{\infty} \frac{d\gamma}{\gamma^2} n_e(\gamma) g_{\rm iso}\left(\frac{\epsilon_1}{4\gamma^2\epsilon}\right), \tag{10}$$

where, ϵ_1 is the scattered photon energy, $f(\epsilon)$ is the photon distribution function, $n_e(\gamma)$ is the electron distribution function and $g_{\rm iso}(x) = \frac{2}{3}(1-x)$ for isotropic photon distribution in the jet-comoving frame. We consider the simple case in which the incident photons have a synchrotron/piecewise power-law energy distribution,

$$f_{in}(\epsilon) = f_0 \begin{cases} (\epsilon/\epsilon_0)^a, & \epsilon < \epsilon_0 \\ (\epsilon/\epsilon_0)^{-b}, & \epsilon > \epsilon_0 \end{cases} \tag{11}$$

and the electrons are mono-energetic with $n_e(\gamma) = n_0 \delta(\gamma - \gamma_0)$. Substituting $x = 4\gamma_0^2 \epsilon/\epsilon_1$ for relativistic electrons yields

$$\frac{dE}{dV dt d\epsilon_1} = 2c\sigma_T n_0 \int_1^{\infty} \frac{dx}{x^2} \left(1 - \frac{1}{x}\right) f\left(\frac{\epsilon_1 x}{4\gamma_0^2}\right). \tag{12}$$

For photons below peak energy $\epsilon_1 < 4\gamma_0^2\epsilon_0$, we can further define $\epsilon_1/4\gamma_0^2 = \eta\epsilon_0$ with $\eta < 1$. For low energy photons with $\eta \ll 1$, if the incident photons have a hard spectrum with $0 < a < 1$, the scattered photon distribution $f_{sc}(\epsilon_1) \propto dE/(dVdtd\epsilon_1) \propto \eta^a \propto \epsilon_1^a/(\gamma_0^{2a}\epsilon_0^a)$ is the same as that of the incident photons. However, for a softer low energy incident photon spectrum with $a \geq 1$ and $\eta \ll 1$, we obtain $f_{sc}(\epsilon_1) \propto dE/(dVdtd\epsilon_1) \propto \epsilon_1$. Therefore, after single scattering of synchrotron photons with broken power-law energy distribution, the low energy spectrum is unaffected for hard spectra with $a < 1$ whereas $f_{sc}(\epsilon) \propto \epsilon$ for softer spectra. For photons above peak energy $\epsilon_1 > 4\gamma_0^2\epsilon_0$ and $\eta \gtrsim 1$. This gives $dE/(dVdtd\epsilon_1) \propto \epsilon_1^{-b}/(\gamma_0^{-2b}\epsilon_0^{-b})$, same as the incident photon spectrum. For fast cooled synchrotron photon spectrum, we have $a = 2$ and $b = -1$, and the scattered photon distribution after single scattering is

$$f_1(\epsilon) = f_{sc}(\epsilon) \propto f_0 \begin{cases} (\epsilon/\epsilon_0)^1, & \epsilon < \epsilon_0 \\ (\epsilon/\epsilon_0)^{-1}, & \epsilon > \epsilon_0. \end{cases} \tag{13}$$

In reality, however, each photon experiences $\sim 2\tau_{in}$ scatterings on an average before escaping the photosphere.

5.2. *Photon distribution after repeated scatterings*

With $f_1(\epsilon)$ as the incident photon distribution, we can now extend the same formalism to calculate the photon spectrum after subsequent scattering events assuming that the electron and photon distributions remain isotropic in the jet-comoving frame. The low and the high energy spectrum after each photon in the jet has undergone exactly two scatterings is

$$f_{2,l}(\epsilon_1) = 2c\sigma_T n_0 f_0 \left(-\eta \ln\eta + \frac{2}{3}\eta^2 - \frac{1}{2}\eta\right) \propto \frac{\epsilon_1}{4\gamma_0^2\epsilon_0} \ln\left(\frac{\epsilon_1}{4\gamma_0^2\epsilon_0}\right),$$

$$f_{2,u}(\epsilon_1) = 2c\sigma_T n_0 f_0 \int_1^\infty dx \frac{1}{x^2}\left(1 - \frac{1}{x}\right)\eta^{-1}x^{-1} \propto \gamma_0^2\epsilon_0/\epsilon_1.$$

The scattered photon spectrum is then

$$f_2(\epsilon) \propto f_0 \begin{cases} (\epsilon/\epsilon_0)\ln(\epsilon/\epsilon_0), & \epsilon < \epsilon_0 \\ (\epsilon/\epsilon_0)^{-1}, & \epsilon > \epsilon_0. \end{cases} \tag{14}$$

After each photon has undergone exactly three scatterings, the low and high energy spectra are given as

$$f_{3,l}(\epsilon_1) \propto \frac{\epsilon_1}{4\gamma_0^2\epsilon_0}\left[\ln\left(\frac{\epsilon_1}{4\gamma_0^2\epsilon_0}\right)\right]^2,$$

$$f_{3,u}(\epsilon_1) = 2c\sigma_T n_0 f_0 \int_1^\infty dx \frac{1}{x^2}\left(1 - \frac{1}{x}\right)\eta^{-1}x^{-1} \propto \gamma_0^2\epsilon_0/\epsilon_1,$$

and the scattered photon spectrum is

$$f_3(\epsilon) \propto f_0 \begin{cases} (\epsilon/\epsilon_0)\left[\ln(\epsilon/\epsilon_0)\right]^2, & \epsilon < \epsilon_0 \\ (\epsilon/\epsilon_0)^{-1}, & \epsilon > \epsilon_0 \end{cases} \tag{15}$$

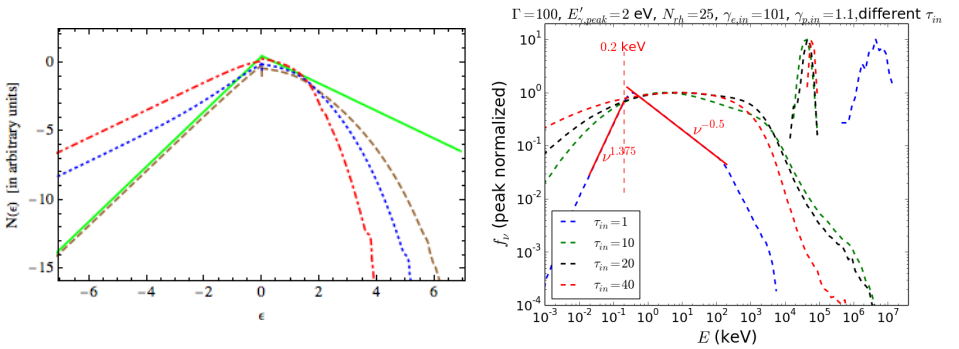

Fig. 4. **Effect of geometrical broadening on the photon spectrum for increasing optical depth.** *Left panel:* IC spectrum for synchrotrom photons with energy $\epsilon_0 = 1$ and Maxwellian electrons with peak energy $\gamma_{e,0} = 1.1$. The solid green line, brown dashed line, blue dotted line and red dot-dashed lines are the scattered photon spectra after $N = 0, 1, 2$ and 5 scatterings, respectively. *Right panel:* MCRaT simulations showing the effect of geometrical broadening on the photon spectrum at $\tau_{in} = 1, 10, 20, 40$ for $(N_{rh}, \gamma_{e,in}) = (25, 101)$ and $\gamma_{p,in} = 1.1$. For these simulations, we consider input parameters $L = 10^{52}$ erg/s, $E'_{\gamma,peak} = 2$ eV and $\Gamma = 100$.

We can generalize the above results further for $N \sim 2\tau_{in}$ scatterings per photon

$$f_N(\epsilon) \propto f_0 \begin{cases} (\epsilon/4\gamma_0^2\epsilon_0)\left[\ln(\epsilon/4\gamma_0^2\epsilon_0)\right]^{N-1}, & \epsilon < \epsilon_0 \\ (\epsilon/4\gamma_0^2\epsilon_0)^{-1}, & \epsilon > \epsilon_0 \end{cases} \tag{16}$$

In Figure 4, we show how the photon spectrum is affected by Comptonization with electrons as τ_{in} and number of scatterings increase. In the left panel, the IC scattered photon spectrum for fast cooled synchrotron seed photons (Equation 11, with $a = 2$ and $b = -1$) with energy $\epsilon_0 = m_e c^2$ and Maxwellian electrons with peak energy $\gamma_{e,0} = 1.1$ is shown for scattering orders $N = 0, 1, 2, 5$. As predicted by equation (16), the photon spectrum becomes gradually softer below peak energy as the scattering order increases. The photons scattering off Maxwellian electrons with fixed energy get thermalized at equilibrium to attain a high-energy exponential tail for large optical depths/scatterings. Furthermore, there is gradual flattening of the low-energy spectrum with increase in scattering order N.

In the right panel of Figure 4, we present the MCRaT simulation results for $E_{\rm inj,cr} = 2500\ m_e c^2$ and different optical depths $\tau_{in} = 1, 10, 20, 40$. The number of repeated dissipation events in the jet are $N_{rh} = 25$ with initial photon/electron/proton energy $E'_{\gamma,peak} = 2$ eV/$\gamma_{e,in} = 101$/$\gamma_{p,in} = 1.1$ and jet parameters $L = 10^{52}$ erg/s and $\Gamma = 100$. With increase in scattering order ($\propto \tau_{in}$), the high energy photon spectrum becomes steeper with a simultaneous decrease in $E_{\gamma,peak}$. These photons then populate the low energy spectrum and extend the non-thermal tail to energies much lower than $E_{\gamma,peak} \sim 0.2$ keV. The photon spectra from simulations are also considerably broader compared to the analytical results for similar values of N.

6. Summary and conclusions

We have utilized our MCRaT photospheric code to explain the distinct non-thermal behaviour of GRB prompt emission spectrum, $f_\nu \propto \nu^0 / f_\nu \propto \nu^{-1.2}$ at low/high photon energies along with observed peak energy at $E_{\gamma,peak} \sim 300$ MeV. For our simulations, we considered Comptonization of fast cooled synchrotron photons with Maxwellian electrons and for photon to particle number ratio $N_\gamma/N_e \sim 10^5$. The jet electrons are accelerated by two different mechanisms: 1. continuous energy transfer via Coulomb collisions with mono-energetic protons, 2. repeated episodic energy dissipation events that are equally spaced over time and accelerate particles back to their initial energies.

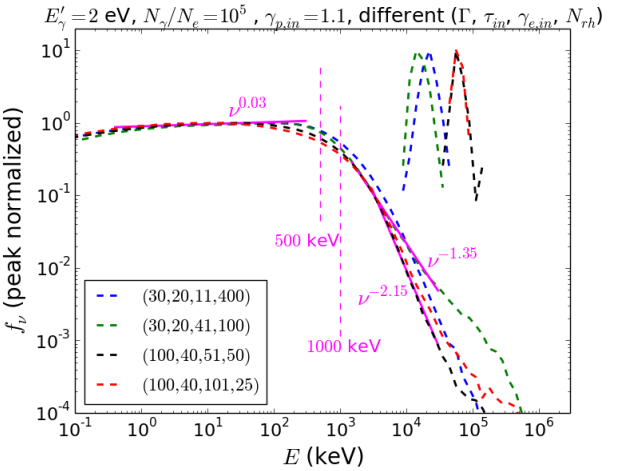

Fig. 5. **MCRaT simulation results with the best set of parameters for a jet with $N_\gamma/N_e = 10^5$.** The relativistic jet with $L = 10^{52}$ erg/s has photons with $E'_{\gamma,\rm peak} = 2$ eV and protons with $\gamma_{p,\rm in} = 1.1$. The energy injection necessary in order to produce an output photon spectrum with the observed Band-like spectral properties depends on $\tau_{\rm in}$ and Γ. Here we consider $E_{\rm inj} = 4000/2500\ m_e c^2$ for $\Gamma = 30/100$ and $\tau_{\rm in} = 20/40$, for two distinct electron energies $\gamma_{e,\rm in} = (11, 41)/(51, 101)$.

The parameters that significantly affect the spectral properties for a given N_γ/N_e are $E_{\rm inj}(\gamma_{e,\rm in}, N_{\rm rh})$, Γ and $\tau_{\rm in}$. Figure 5 shows the most probable parameter set that gives output photon spectrum with $(\alpha, \beta, E_{\gamma,\rm peak})$ very similar to the observed GRB prompt spectrum. The photons/protons in these simulations are initialized with energies $E'_{\gamma,\rm peak} = 2$ eV/$\gamma_{p,\rm in} = 1.1$ for jet parameters $L = 10^{52}$ erg/s, $N_\gamma/N_e = 10^5$ and $\Gamma \sim 30 - 100$. The particles are injected with energy $E_{\rm inj,cr} \sim 2500 - 4000\ m_e c^2$ per electron for a range of $\tau_{\rm in} \sim 20 - 40$. For smaller $\tau_{in} \sim 20$ and $\Gamma \sim 30$, $(\alpha, \beta, E_{\gamma,peak}) \sim (0, -1.4, 1$ MeV) is obtained with $E_{inj,cr} \sim 4000\ m_e c^2$ and $\gamma_{e,in} \gtrsim 40$. Although $\alpha \sim 0$ and $E_{\gamma,peak} \sim 500$ keV for $E_{inj,cr} \sim 2500\ m_e c^2$ at larger $\tau_{in} \sim 40$ and $\Gamma \sim 100$, the high energy spectrum is significantly steeper than the observed prompt spectrum with $\beta \sim -2.1$, especially for $\gamma_{e,in} \lesssim 50$.

The main results of this work can be summarised as:

(1) The electrons cool down rapidly to non-relativistic energies in the absence of jet dissipation events. This entails energy injection into the jet particles via either (continuous) Coulomb collisions or (episodic) sub-photospheric dissipation events. However, for Coulomb heating, the protons lose a considerable fraction of their energy within $\sim t_{dyn}$, for $\tau_{in} \gtrsim 10$, to attain non-relativistic energies. Therefore, continuous energy injection by protons is not sufficient to maintain electrons at $\gamma_e \sim \gamma_{e,crit}$.

(2) Energy injection can be achieved with episodic sub-photospheric dissipation events which can keep the electrons at energies $\gamma_e \gtrsim \gamma_{e,crit}$ provided that they are sufficiently energetic and frequent. For large $E_{\rm inj}$, the photon peak energy $E_{\gamma,\rm peak} \gg E_{\gamma,\rm obs} \sim 300$ keV, while for large $\tau_{\rm in}$, $E_{\gamma,\rm peak} \ll E_{\gamma,\rm obs}$ due to significant adiabatic loss. From MCRaT simulations, we quantify the $E_{inj} - \tau_{\rm in}$ correlation: injected energy $E_{inj,cr} = 4000/2500\ m_e c^2$ per electron for initial optical depth $\tau_{in} = 20/40$.

(3) In the output photon spectrum, α critically depends on $E_{\rm inj}$ whereas β and $E_{\gamma,\rm peak}$ are almost entirely determined by $\tau_{\rm in}$. With an increase in $\tau_{\rm in}$, $E_{\gamma,\rm peak}$ decreases and the high-energy photon spectrum becomes steeper. Additionally, $|\beta|$ also increases with decrease in initial electron energy $\gamma_{e,in}$ for fixed $E_{\rm inj,cr} = N_{rh,cr}(\gamma_{e,in} - 1)\ m_e c^2$. We find that $E_{\gamma,\rm peak} \sim E_{\gamma,\rm obs}$ only for smaller $\Gamma \sim 30$ - while larger $\Gamma \sim 100$ gives $E_{\gamma,peak} \sim 500$ keV at $\tau_{in} \sim 40$, the high energy photon spectrum is considerably steeper than observed.

(4) For isotropic electrons scattering isotropic photons, the scattered photon energy distribution can be analytically evaluated for lower order scatterings, given the electron and photon energy distributions. For Comptonization of synchrotron photons with Maxwellian electrons, $\alpha \sim 0$ behaviour is retained at low energies whereas $f_\nu \propto e^{-\nu}$ at high energies. Qualitatively, the low-energy non-thermal dependence is obtained from multiple scatterings and subsequent geometrical broadening of the spectrum whereas the high-energy power-law dependence is attributed to repeated episodic and continuous energy injection events.

Monte Carlo simulations of photospheric emission in Gamma Ray Bursts

T. M. Parsotan* and D. Lazzati
Department of Physics, Oregon State University, Corvallis, OR 97331, USA
**E-mail: parsotat@umbc.edu*

The study of Gamma Ray Bursts (GRBs) has the potential to improve our understanding of high energy astrophysical phenomena. In order to reliably use GRBs to this end, we first need to have a well-developed grasp of the mechanism that produces the radiation within GRB jets and how that relates to their structure. One model for the emission mechanism of GRBs invokes radiation produced deep in the jet which eventually escapes the jet at its photosphere. While this model has been able to explain a number of observed GRB characteristics, it is currently lacking in predictive power and in ability to fully reproduce GRB spectra. In order to address these shortcomings of the model, we have expanded the capabilities of the MCRaT code, a state of the art radiative transfer code that can now simulate optical to gamma ray radiation propagating in a hydrodynamically simulated GRB jet. Using the MCRaT code, we have constructed mock observed light curves, spectra, and polarization from optical to gamma ray energies for the simulated GRBs. Using these mock observables, we have compared our simulations of photospheric emission to observations and found much agreement between the two. Furthermore, the MCRaT calculations combined with the hydrodynamical simulations allow us to connect the mock observables to the structure of the simulated GRB jet in a way that was not previously possible. While there are a number of improvements that can be made to the analyses, the steps taken here begin to pave the way for us to fully understand the connection between the structure of a given GRB jet and the radiation that would be expected from it.

Keywords: Gamma-rays: Bursts; relativistic outflows; radiation transfer.

1. Introduction

Gamma Ray Bursts (GRBs) typically produce high energy X-ray and gamma-ray radiation that is detected within the first few tens of seconds of the event. The origin of this so called prompt emission is still not well understood even after decades of investigation. The two most common models that are used to describe the prompt emission of GRBs either employ synchrotron emission from jets with magnetic fields[1–4] or emission from the photospheres of GRB jets.[5–15]

Each model has its own advantanges and disadvantages allowing them to describe GRB observations at gamma-ray and X-ray energies in varying capacities. Models that rely on synchrotron emission are able to account for the non-thermal characteristics of GRB spectra[4,16] but are unable to fully account for various GRB observational relationships such as the Amati[17] and Yonetoku[18] relations.[1] The photospheric model on the other hand is able to reproduce the Amati and

Yonetoku relations[10,12,13,15,19,20] but has issues with reproducing typical GRB spectral parameters.[12,13] In order to fully distinguish between these models additional data at different wavelengths is needed.

There have been a number of optical prompt emission detections that can be used for the purpose of model comparison (see[21] and references therein). Additionally, there has been one detection of optical prompt polarization[22] that can also be used in comparison with optical polarization predictions obtained from synchrotron and the photospheric model calculations. The synchrotron model has traditionally been favored by these optical prompt detections[23–27] however the photospheric model has not been fully explored in its ability to reproduce these optical prompt detections.

The ability to simulate radiation signatures produced under the photospheric model has recently been improved.[11–15,21,28,29] These analyses have combined the realistic treatment of radiation with hydrodynamically simulated time-dependent GRB jets. As a result, studies of how the GRB jet structure affects the detected radiation signatures are now possible. With the ability of these state-of-the-art radiative transfer calculations to also calculate the effects of cyclo-synchrotron emission and absorption,[21,29] these types of analyses are also now possible from optical to gamma-ray energies. In this proceeding, we highlight the results of conducting radiative transfer calculations of hydrodynamically simulated GRB jets and the construction of mock observations from these calculations. We show how the mock observables can be related to the structure of the simulated GRB jets and how these analysis can help us interpret GRB observations under the photospheric model. Finally, we conclude with a summary and highlight ways that these types of global radiative transfer calculations can push the field forward.

2. Methods

2.1. *The MCRaT Code*

We have used the open-source **M**onte **C**arlo **Ra**diation **T**ransfer (MCRaT) code[30] to analyze the evolution of radiation trapped within hydrodynamical simulations of GRB jets. The MCRaT code considers photons in the astrophysical outflow that interact via Compton scattering including the effects of the full Klein-Nishina cross section with polarization. The code also considers photons that have been absorbed and emitted in the outflow due to cyclo-synchrotron (CS) emission and absorption. We summarize the algorithm here, however detailed descriptions of the code are outlined in[21] and.[29] As is outlined in Figure 1, the code loads a SRHD simulation frame and injects photons into the simulated GRB jet where the optical depth $\tau > 100$. The code will calculate the mean free paths of each photon in the simulation in order to determine which will scatter. After this calculation, MCRaT advances the simulation time to correspond to when the scattering will occur and propagates each photon by a distance corresponding to the amount of time passing in the simulation. The code then conducts the scattering considering the full Klein-Nishina

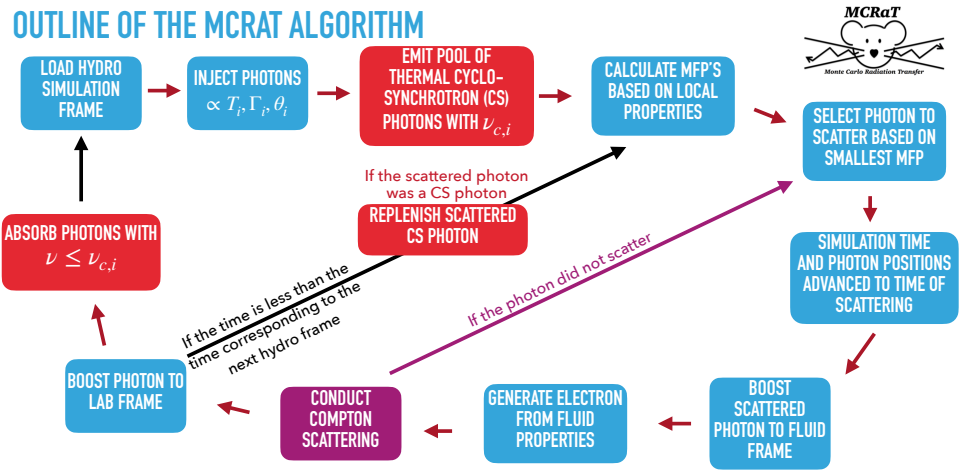

Fig. 1. The outline of the MCRaT code, see text for in depth explanation.

cross section with polarization, which means that the photons have some probability of not scattering in the electron rest frame. If the chosen photon ends up not being scattered, MCRaT chooses the next photon that would have scattered and advances the simulation time and the location of each photon. If the photon is scattered, then the new four momentum and polarization of the photon is calculated. The code continues to scatter photons until the time in MCRaT corresponds to the time in the next SRHD simulation frame. If CS emission and absorption is also taken into account in the simulation then the steps in the red boxes are taken which numerically simulate CS emission and absorption processes in MCRaT.

2.2. *Mock Observations*

With a given MCRaT simulation completed, we use the open-source ProcessMCRaT code[31] to produce mock observed light curves, spectra, and polarization measurements that can be compared to actual GRB observations on a more equal basis. This code allows photons from an MCRaT simulation to be binned in time and energy in order to produce the mock observables, similar to how actual photons measured in a given GRB event are binned. Detailed descriptions of how we construct the mock observable quantities for observers at various viewing angles with respect the jet axis, $\theta_{\rm v}$, can be found in.[12–14,21] We use the same gamma-ray and optical energy ranges as in.[29] The gamma-ray mock observables are calculated from photons with energies between 20-800 keV which corresponds to the polarimetry energy range of POLAR-2.[32] The optical mock observables are calculated from photons with energies between 1597-7820 $\mathring{A}$ ($\sim 1.5 - 7.7$ eV), which aligns with the Swift UVOT White bandpass.[33,34]

The way that we connect the mock observables to the structure of the simulated GRB jets is through equal arrival time surfaces (EATS)[7,35,36] of the photons in the GRB jet. For a given time bin, in the mock observed light curve, we can calculate surfaces that would be emitting photons towards a given observer's line of sight. These surfaces are calculated following the method of,[14] who describe the procedure for constructing these EATS.

2.3. *The Simulation Set*

The MCRaT code was used to analyze a set of two special relativistic hydrodynamical simulations (SRHD) of GRB jets. These SRHD simulations were conducted using the FLASH hydrodynamics code[37] and their properties are outlined in.[14,21,29] These two SRHD simulations are referred to as the *16TI* and *40sp_down* simulations and they represent GRB jets that have a time-constant and time-variable injection of energy, respectively.

3. Results

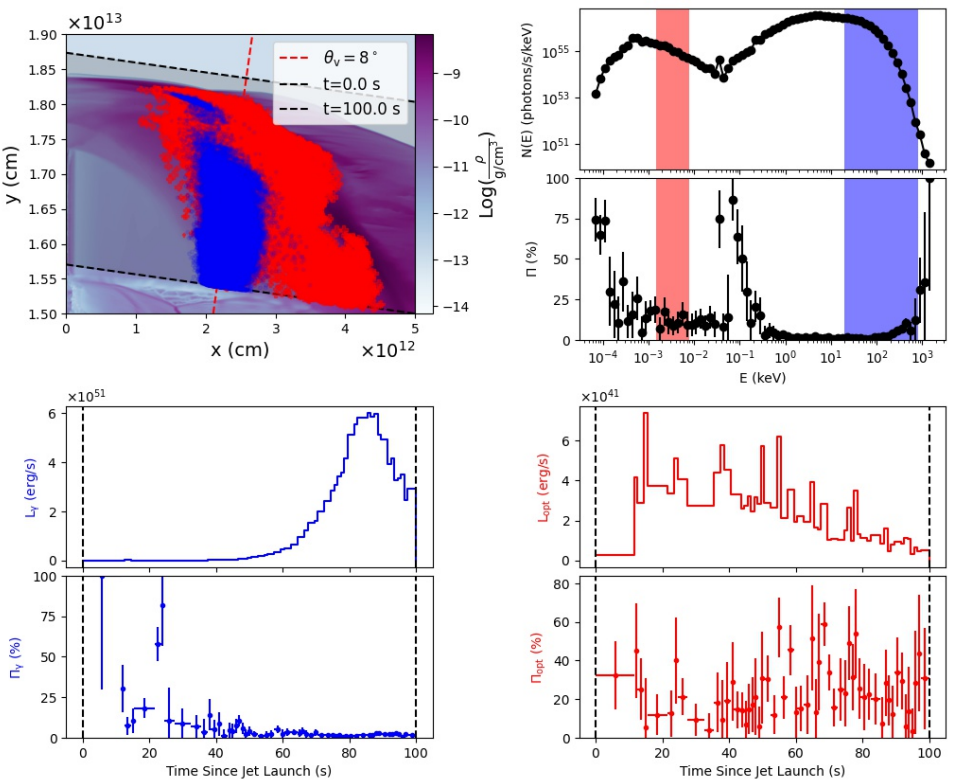

Fig. 2. The relation between the mock observed quantities and the jet structure of the *16TI* simulation for $\theta_v = 8°$. See text for full description.

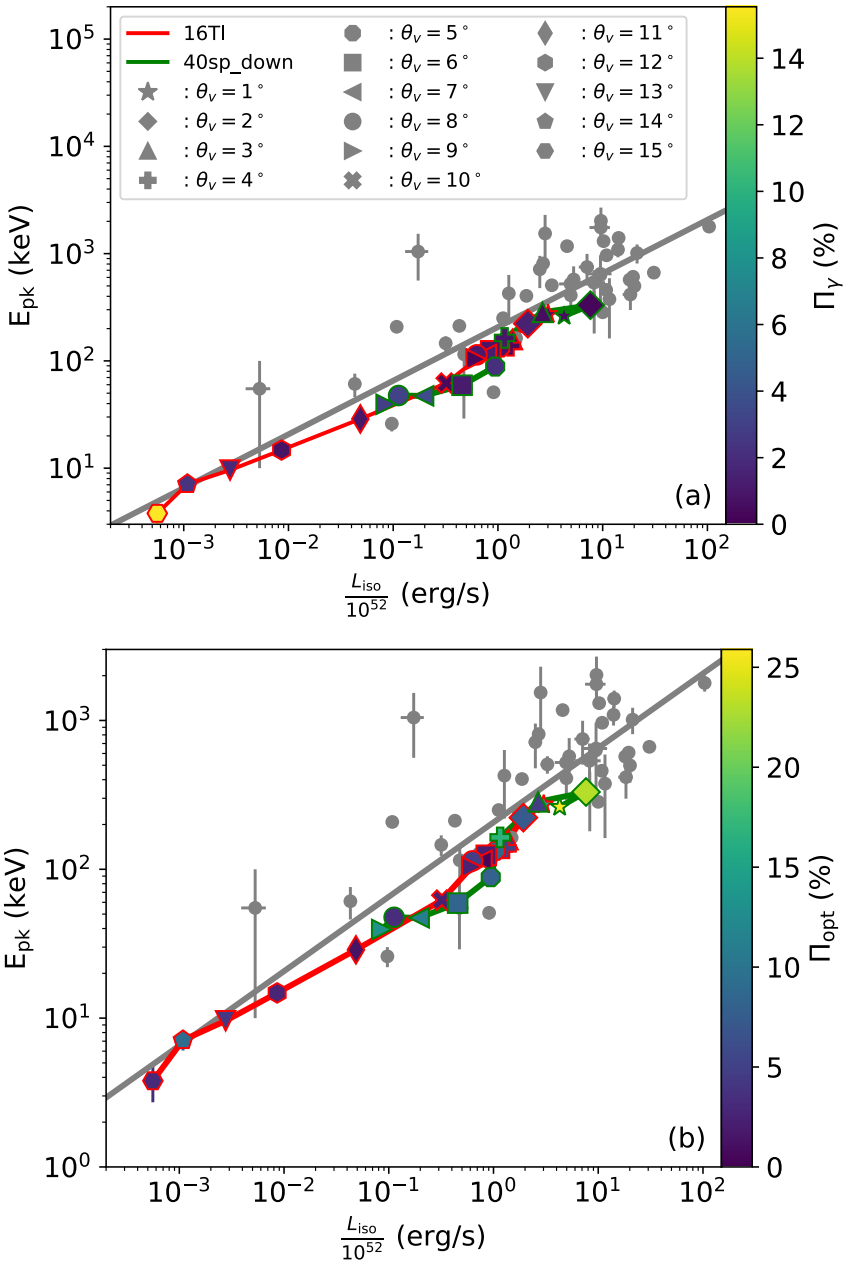

Fig. 3. The *16TI* and *40sp_down* simulations plotted alongside the Yonetoku relationship[18] in red and green lines and marker outlines, respectively. In Figure (a), the fill color of the marker denotes the mock observed time-integrated Π_γ while in Figure (b) the fill color shows the time-integrated MCRaT Π_{opt}. The different marker shapes for the MCRaT simulations show the placement of the simulations on the Yonetoku relationship as determined by observers at various θ_v. In each panel the observational relationship is shown as the grey solid line and observed data from[38] are plotted as grey markers. Figure adapted from.[29]

Our MCRaT simulations have shown that optical and gamma ray photons probe different regions of GRB outflows under the photospheric model, as is shown in Figure 2. Here, we show all the photons that have been detected by an observer located at $\theta_{\rm v} = 8^\circ$ in optical and gamma-ray energies. The top left panel shows the location of each photon in relation to the density structure of the SRHD simulated GRB jet. The density of the jet is shown as a pseudocolor plot where darker colors show denser regions and the dashed red line denoted the line of sight of the observer at $\theta_{\rm v} = 8^\circ$. The optical photons are shown in red while gamma-ray photons are depicted in blue. Furthermore, the photon markers are translucent allowing us to identify regions of the jet where the photons are densely located (due to the concentration of blue or red). Additionally, the markers are different sizes in order to show the weight of each photon in the calculation of the various mock observable quantities. The top right panel shows the time integrated spectrum of these photons with highlighted red and blue regions that highlight the energy ranges which were used to calculate the optical and gamma-ray light curves (L_γ and $L_{\rm opt}$) and polarizations (Π_γ and $\Pi_{\rm opt}$). These time-resolved mock observables are shown in the bottom 4 panels. These analysis allow us to connect the mock observables of light curves, spectra, and polarizations with the locations of where the photons are within the jet and what the jet structure is at those locations. As is shown in Figure 2, the optical photons are distrubuted widely about the observer's line of sight with their locations being focused at the dense jet-cocoon interface (JCI;[39]). The gamma-ray photons instead are mostly concentrated along the observer's line of sight with the exception of some gamma-ray photons being located near the core of the jet. Thus, optical prompt emission probes the dense JCI while the gamma-ray emission probes the portion of the jet that is directly along the observer's line of sight.

The results of our MCRaT simulations can also be used to assess how well the simulations reproduce various observational relationships, such as the Yonetoku relation,[18] and make additional predictions that can be tested against data. Figure 3 shows the comparison between the *16TI* and *40sp_down* simulations, in red and green marker edge colors and lines respectively, and the Yonetoku relation. Various observed GRBs from[38] are also shown as grey circles. We also show the time-integrated Π_γ and $\Pi_{\rm opt}$ in Figure 3(a) and (b) respectively, through the fill-color of each marker. In each panel, we see that both the *40sp_down* and *16TI* simulations are able to recover the normalization and slope of the Yonetoku relation for a variety of $\theta_{\rm v}$. With this success of the photospheric model, we can also now use the simulated polarization mock observations to make predictions. We find that the time-integrated Π_γ should increase as $\theta_{\rm v}$ increases which has been found in other studies.[40,41] Thus, bursts that are bright and energetic (in the top right of the Yonetoku relation) should have low time-integrated Π_γ. On the other hand, the time-integrated $\Pi_{\rm opt}$ should be larger for $\theta_{\rm v}$ that are close to the jet axis. As a result, we would expect that bursts located in the top right of the Yonetoku relation would have large time-integrated $\Pi_{\rm opt}$.

4. Conclusion

Using the MCRaT radiative transfer code, we have conducted post-processing analysis of the radiation expected from time-dependent special relativistic hydrodynamic simulations of GRB jets. These global radiative transfer simulations allow for the connection between observed radiation signatures and the structure of the GRB jet, which was not possible prior to these types of analysis. These analyses are commonplace in other areas of astrophysics such as galaxy formation and have proved fruitful in connecting radiation processes to the structure of galaxies and in testing observational data analysis techniques (see e.g.[42] and[43]). While these types of analysis are beginning to emerge in the study of GRBs (see references within), we need widespread adoption of these simulations within the community for any SRHD simulations that have been conducted of GRB jets. This would allow the community to build a library of GRB jet simulations and their associated radiation signatures that can be used in comparison to GRB observations, greatly enhancing our knowledge of GRB jets and the prompt emission.

The photospheric emission in the prompt phase is the natural prediction of the original fireball model for gamma-ray burst (GRB) due to the large optical depth ($\tau > 1$) at the base of the outflow, which is supported by the quasi-thermal components detected in several *Fermi* GRBs. However, which radiation mechanism (photosphere or synchrotron) dominates in most GRB spectra is still under hot debate. The shape of the observed photosphere spectrum from a pure hot fireball or a pure Poynting-flux-dominated outflow has been investigated before. In this work, we further study the photosphere spectrum from a hybrid outflow containing both a thermal component and a magnetic component with moderate magnetization ($\sigma_0 = L_P/L_{\rm Th} \sim 1 - 10$), by invoking the probability photosphere model. The high-energy spectrum from such a hybrid outflow is a power law rather than an exponential cutoff, which is compatible with the observed Band function in large amounts of GRBs. Also, the distribution of the low-energy indices (corresponding to the peak-flux spectra) is found to be quite consistent with the statistical result for the peak-flux spectra of GRBs best-fitted by the Band function, with similar angular profiles of structured jet in our previous works. Finally, the observed distribution of the high-energy indices can be well understood after considering the different magnetic acceleration (due to magnetic reconnection and kink instability) and the angular profiles of dimensionless entropy with the narrower core.

Keywords: Gamma-ray burst: general – radiation mechanisms: thermal – radiative transfer – scattering

1. Introduction

After decades of researches, the radiation mechanism of GRB prompt emission is still unclear.[30–33] The photospheric emission model seems to be a promising scenario.[12,19–21,24,27] The photospheric emission model naturally interprets the clustering of the peak energies[14] and the high radiation efficiency[16] observed.

Indeed, a quasi-thermal component has been found in great amounts of BATSE GRBs[25] and several *Fermi* GRBs (GRB 090902B[1]). To account for the broad spectra of other GRBs, the quasi-thermal spectrum need to be broadened. Two different mechanisms of broadening have been proposed theoretically, i.e., the subphotospheric dissipation[7,24] and the geometric broadening.[4,17,19,20,22] This geometric broadening, namely the probability photosphere model, is the result of the fact that photons can be last scattered at any place (r, Ω) inside the outflow if only the electron exists there.[3,22,23] Then, the observed photosphere spectrum is the superposition of a series of blackbodies with different temperature, thus broadened.

In studies on the probability photosphere model till now,[4,17,20] the jet is accelerated solely by the radiative pressure of the thermal photons. However, the magnetically driven acceleration[5,7] may also play an important role in the real situation, which has not been properly considered in the framework of the probability photosphere model. In this work we study the photospheric emission spectrum within the framework of the probability photosphere model for a hybrid relativistic outflow, which contains a thermal component and a magnetic component, including both the thermally and magnetically driven acceleration.

The paper is organized as follows. In Section 2, we describe the calculations of the photospheric emission spectrum for a hybrid outflow within the probability photosphere model, including the energy injections of impulsive injection and more reasonable continuous wind. The calculated spectral results and parameter dependencies are shown in Section 3. The conclusions are summarized in Section 4.

2. Probability photosphere emission from a hybrid jet

2.1. *Hybrid jet and its dynamics*

A hybrid jet is composed of a thermal component and a magnetic component, which could be described by the dimensionless entropy η and the initial magnetization parameter σ_0. The dynamics for a hybrid jet may be approximated as

$$\Gamma(r) = \begin{cases} \frac{r}{r_0}, & r_0 < r < R_{\rm ra}; \\ \Gamma_{\rm ra}\ (\frac{r}{R_{\rm ra}})^{\delta}, & R_{\rm ra} < r < R_c; \\ \Gamma_c, & r > R_c, \end{cases} \tag{1}$$

where r_0 is the radius at the jet base, $\Gamma_{\rm ra} = \max(\eta, [\eta(1+\sigma_0)]^{1/3})$ is the Lorentz factor at $R_{\rm ra}$, $\Gamma_c \simeq \eta(1+\sigma_0)$ is the coasting Lorentz factor, $R_{\rm ra}$ is the rapid acceleration radius and R_c is the coasting radius.

2.2. *Time-resolved spectra from probability photosphere emission*

2.2.1. *Impulsive injection*

For the probability photosphere model, the observed spectrum is a superposition of a series of blackbodies emitted from any place in the outflow with a certain probability, which is calculated by

$$F_\nu(\nu, t) = \frac{N_0}{4\pi d_L^2} \iint P_1(r,\mu) P_2(\nu, T) h\nu \times \delta(t - \frac{ru}{\beta c}) d\mu dr, \tag{2}$$

where $u = 1 - \beta\cos\theta$, and $N_0 = L_w/2.7k_{\rm B}T_0$ is the number of photons injected impulsively at the base of the outflow, $P_1(r,\mu)$ represents the probability density function for the final scattering to occur at the coordinates (r,θ), $\mu = \cos\theta$, $P_2(\nu, T)$ represents the probability for a photon of the observed frequency ν last-scattered at (r,θ) with the observer frame temperature of T.

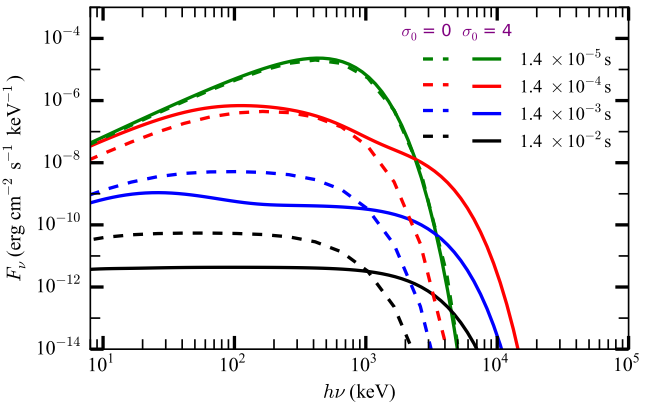

Fig. 1. The time-resolved spectra of impulsive injection for the jet with and without magnetization. The solid lines show the calculated time-resolved spectra for the hybrid jet with a hot fireball component ($\eta = 400$) and a cold Poynting-flux component (σ_0= 4). Also, a total outflow luminosity of $L_w = 10^{53}$ erg s^{-1} is assumed, base outflow radius $R_0 = 3 \times 10^8$ cm, and luminosity distance $d_{\rm L} = 4.85 \times 10^{28}$ cm ($z = 2$). Different colors represent different observational times. For comparison, the dashed lines illustrate the time-resolved spectra calculated for the jet without magnetization.[4] Obviously, at later times the time-resolved spectra extend to much higher energy and a power-law component emerges in the low-energy end.

2.2.2. *Continuous wind*

It is more realistic to consider the continuous wind from the central engine since the GRBs have relatively long duration (> 1 s). For a layer ejected from $\hat{t}$ to $\hat{t} + d\hat{t}$, the observed spectrum at the observer time t is

$$\hat{F}_\nu(\nu, t, \hat{t}) = \frac{N_0}{4\pi d_L^2} \iint P_1(r, \mu) P_2(\nu, T) h\nu \times \delta(t - \hat{t} - \frac{ru}{\beta c}) d\mu dr. \tag{3}$$

Then, integrating over all the layers, we obtain the observed time-resolved spectrum to be

$$F_\nu(\nu, t) = \int_0^t \hat{F}_\nu(\nu, t, \hat{t}) d\hat{t}. \tag{4}$$

3. Calculated results

3.1. *Impulsive injection*

The calculated time-resolved spectra are shown in Figure 1 (the solid lines). It is found that at the later times (the high-latitude emission dominates) the time-resolved spectra firstly show a power-law shape extending to a much higher energy than the early-time blackbody. Then, the power-law component vanishes gradually towards the low-energy end and the peak energy on the high-energy end remains constant.

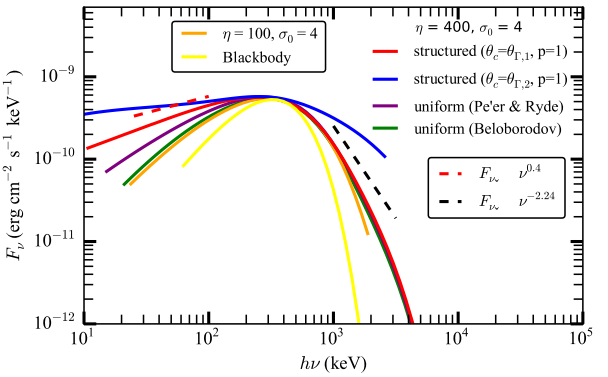

Fig. 2. The time-resolved spectra at later times ($t \geq 1$ s) of a continuous wind for the hybrid jet with magnetization σ_0= 4 and various values or angular profiles of dimensionless entropy η. Here, $\theta_{\Gamma,1} = 1/400$ and $\theta_{\Gamma,2} = 1/4000$. All the time-resolved spectra have been normalized to the same peak energy and peak flux as the case of $\eta = 400$ and σ_0= 4 (green line) to compare clearly the low-energy and high-energy indices. For comparison, the yellow line shows the spectrum of blackbody. Also, the red and black dashed lines represent respectively the average low-energy index (−0.6) and high-energy index (−3.24) fitted with the Band function for the time-resolved spectra of a large sample of single pulses.[29]

3.2. *Continuous wind*

For the continuous wind with constant wind luminosity, the spectrum at a later time ($t \geq 1$ s) which corresponds to the observed peak-flux spectrum is calculated by Equation (4). This calculated time-resolved spectrum, with the same parameters as Figure 1 ($\eta = 400$, σ_0= 4) is illustrated by the green lines (with the probability density function introduced in[3]) in Figure 2. Apparently, the spectrum on the high-energy end is a power law rather than an exponential cutoff, which is the natural result of the power-law component extending to much higher energy in Figure 2.

Furthermore, we calculate the spectrum (with the probability density function described in[23]) for the case of the dimensionless entropy η of a lateral structure, with which the observed typical low-energy spectral index $\alpha \approx -1$ can be obtained for the unmagnetized jet under the framework of the probability photosphere model.[17,20] The considered angular profile consists of an inner constant core with width θ_c and the outer power-law decreased component with power-law index p. Note that an angle-independent luminosity is considered, because the spectrum expected to be observed is formed by the photons making their last scattering at approximately $\lesssim 5/\,\Gamma_0$ (as shown in[17]) and the isotropic angular width for Lorentz factor $\theta_{c,\Gamma}$ is likely to be much smaller than the isotropic angular width for luminosity $\theta_{c,L}$.[6,13,15,26,34] The red line in Figure 2 represents the calculated spectrum for a hybrid jet with $\theta_c = \theta_{\Gamma,1} = 1/400$ and $p = 1$, corresponding to the typical value $\alpha \sim -1$ for an unmagnetized jet. While the blue line is the spectrum for hybrid jet with $\theta_c = \theta_{\Gamma,2} = 1/4000$ and $p = 1$, corresponding to the minimum value $\alpha \sim -2$ for unmagnetized jet

(see Figure 7d in[20]). To compare clearly the low-energy and high-energy indices, in Figure 2 the calculated actual time-resolved spectra have been normalized to the same peak energy and peak flux as the case of $\eta = 400$ and $\sigma_0 = 4$.

We then find that the spectrum of the hybrid jet possesses the much harder low-energy spectral index than that of the unmagnetized jet with the same angular profile, $\alpha \sim -0.6$ for $\theta_c = \theta_{\Gamma,1}$, $p = 1$ and $\alpha \sim -1$ for $\theta_c = \theta_{\Gamma,2}$, $p = 1$. The high-energy power-law index β is the same as the uniform case for $\theta_c = \theta_{\Gamma,1}$, $p = 1$ ($\beta \sim -4$, see Figure 3 and the discussion in Section 3.3), and much larger ($\beta \sim -1.6$) for $\theta_c = \theta_{\Gamma,2}$, $p = 1$. In a word, the spectrum of the hybrid jet is analogue to the empirical Band function[2] spectrum, whereas the spectrum of the unmagnetized jet corresponds to the spectrum of the empirical cutoff power-law model,[20] within the framework of the probability photosphere model.

Interestingly, in all the statistical works of a large sample of GRBs,[9–11,14,28] the average low-energy spectral index for the GRBs best-fitted by the Band function is harder ($0.1 \sim 0.3$) than that for the GRBs best-fitted by the cutoff power-law model, for both the time-integrated and the peak-flux spectra. This hardness is quite consistent with our results for the probability photosphere model discussed in the previous paragraph. Also, for the distributions of the low-energy and high-energy indices, our results (corresponding to the peak-flux spectra) are quite similar to the statistical results of the peak-flux spectra for the GRBs best-fitted by the Band function. For the low-energy spectral index, the typical value is $\alpha \sim -0.6$ and the minimum value $\alpha \sim -1$. While for the high-energy spectral index, the maximum value $\beta \sim -1.6$ in our model is close to the statistical result. The typical value $\beta \sim -4$ in our model seems to be much softer than the well-known $\beta \sim -2.5$, which we consider to arise from the assumption of the single pulse, namely without the overlap of the pulses. This consideration is proposed recently,[29] where the time-resolved spectral analysis of a large sample of single pulses has been performed and the average high-energy spectral index ($\beta \sim -3.24$) indeed is found to be much softer. Noteworthily, the average high-energy spectral index $\beta \sim -3.24$ in that work can be well reproduced with our hybrid jet model, by considering the parameter dependence on the power-law index of magnetic acceleration δ (see Figure 3 and the discussion in Section 3.3). In Figure 2, the red and black dashed lines represent the average low-energy index (-0.6) and high-energy index (-3.24) in that work, respectively.

3.3. *Parameter dependence*

In the above discussion, for the magnetically driven acceleration, we only consider the case of magnetic reconnection for the non-axisymmetric rotator.[5] Whereas, for an initially axisymmetric flow, the acceleration can happen through the kink instability.[8,18] Besides, the magnetic acceleration driven by the kink instability seems to be more rapid than the magnetic reconnection case, with a larger power-law index δ of $\sim 2/5$ or even $\sim 1/2$ (see Figure 5 in[8]). Thus, in Figure 3 we compare the

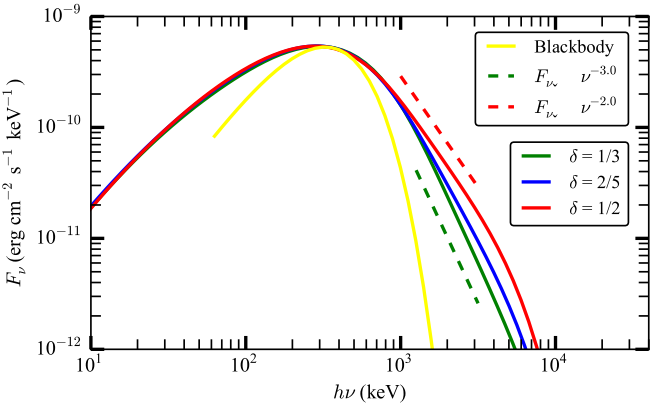

Fig. 3. The calculated time-resolved spectra at later times ($t \geq 1$ s) of continuous wind with different power-law index of magnetic acceleration δ. The green, blue and red lines are for $\delta = 1/3$, $\delta = 2/5$ and $\delta = 1/2$ respectively, along with magnetization $\sigma_0 = 9$. While the green and red dashed lines represent the high-energy spectral index $\beta = -4$ and $\beta = -3$, respectively. The yellow line is the spectrum of blackbody.

calculated spectra of our model for $\delta = 1/3$, $\delta = 2/5$ and $\delta = 1/2$, and find that their high-energy power-law indices are quite different while the low-energy indices remain the same. For $\delta = 1/3$, we have $\beta = -4$; for $\delta = 1/2$, we obtain $\beta = -3$; and β lies between -4 and -3 for $\delta = 2/5$. Surprisingly, this rough distribution of β (-4 to -3) is well consistent with the β distribution of the softer cluster for a large sample of single pulses,[29] where the β distribution seems to show the bimodal distribution with a harder typical cluster (peaks at -2.5) and a softer cluster (peaks at -3.5; see Figure 1 therein).

4. Conclusions

In this paper, by invoking the probability photosphere model we investigate the shape of the photospheric emission spectrum for the hybrid outflow, which contains a thermal component and a magnetic component with moderate magnetization ($\sigma_0 = L_P/L_{\rm Th} \sim 1 - 10$). The following conclusions are drawn.

(1) The photosphere spectrum on the high-energy end is a power law rather than an exponential cutoff.

(2) With the similar angular profiles of the dimensionless entropy η as the unmagnetized jet, considered in previous works,[17,20] the distribution of the low-energy indices (corresponding to the peak-flux spectra) for our photosphere model is quite consistent with the statistical result of the peak-flux spectra for the GRBs best-fitted by the Band function.

(3) The high-energy power-law index β for our photosphere model solely depends on the power-law index of magnetic acceleration δ. Also, the observed β distribution could be well interpreted with the photosphere model in this work.

Photospheric emission from relativistic outflows may originate in two different regimes: photon decoupling within the outflow or radiative diffusion. I show that observed thermal component in the early afterglows of gamma-ray bursts can originate from such diffusive photospheres.

Keywords: Thermal radiation, gamma-ray bursts

1. Introduction

Gamma-ray bursts (GRBs) are strong and short irregular flashes of hard "prompt" radiation, followed by the long lasting fading out smooth "afterglow" emission spanning from sub-TeV energies to radio. Since their discovery a number of dedicated space observatories and ground based telescopes are constantly monitoring the sky daily reporting new bursts and measuring distance to their host galaxies. GRBs come in two kinds[1]: short and long, with their possible progenitors being binary neutron star mergers and collapsing massive stars reaching the endpoint of their evolution, respectively. Extremely large energies released in γ-rays ($\leq 10^{54}$ erg) as well as a short variability time (≤ 10 ms) point to ultrarelativistic outflows giving rise to the observed emission.[2]

The spectrum of the prompt emission is non-thermal, its origin can be traced to the synchrotron mechanism in relativistic shock waves, generated by the relativistic material breaking in the interstellar medium.[3] Photospheric models with possible dissipation of kinetic energy of the outflow are attractive alternative to the synchrotron models since observation of thermal radiation allows for the determination of basic hydrodynamic characteristics of the outflow from which these bursts originate.[4–6] The photons in these models are trapped and advected with the opaque outflow, until it becomes transparent. In many GRBs, a subdominant thermal component was detected during their prompt emission, while in several, such as GRB 090902B observed spectrum is almost thermal.[7,8]

Thermal components are also detected in time resolved spectra during the early afterglow in a number of GRBs.[9–14] So far several mechanisms to generate such

emission are proposed. They include a shock breakout from a progenitor star or a stellar wind[15] and a hot cocoon formed when the relativistic jet emerges from the stellar surface.[16,17] Some authors argue that shock breakouts are not energetic enough and do not last long enough to explain the observed thermal emission,[13] leaving cocoons as a favourite model. In addition, there is an alternative proposal of a cloud or a clump with small mass, accelerated by the GRB outflow.[18]

Most studies dealing with the photospheric emission, e.g.,[19–25] for a review see,[5] adopt the hydrodynamic model of a steady and infinite wind. However, finite duration of GRBs implies finite width of the wind. Winds of *finite duration* are classified as photon thin and photon thick.[4,26,27] Decoupling of photons from plasma in the latter case occurs simultaneously in the entire outflow, while in the former case photons are transported to the boundaries of the outflow by radiative diffusion, just like in nonrelativistic outflows, e.g. in supernova ejecta. Emission in this case originates not at the photospheric radius, but at smaller radii. The photon thick case, corresponding to the steady wind, appears to be justified for typical GRB parameters. Photon thin regime is overlooked in the literature, as it is assumed that at large radii the outflow is spreading[28,29] due to strong velocity gradients initially generated in the outflow, see e.g.[28,29] Such spreading outflows indeed correspond to the photon thick case.[30] However, the origin of these gradients is not clear. Even if initially present, such gradients may be erased in initial phases of expansion, e.g. by oblique shocks or other mechanisms. Hence the outflow can be photon thin. In such a case decoupling of photons from expanding plasma occurs in the diffusive regime.[27]

Radiative diffusion is known to be relevant for expanding ejecta in supernovae explosions.[31] Recently the theory of photospheric emission[27] was further extended.[32] In particular, physical parameters of such outflows were determined using the observational data.

The paper is organized as follows. The definition of relativistic photosphere is recalled in Section 2. Observational properties of diffusive photospheres are discussed in Section 3. The method for determination of physical parameters of the outflow is presented in Section 4. Physical parameters of GRB cocoons are discussed in Section 5. Case studies of GRBs with thermal emission in the early afterglow are reported in Section 6. Discussion and conclusion follow.

2. Relativistic photosphere

Consider a relativistic outflow launched at a radius R_0. The outflow is characterized by its activity time Δt, the luminosity L and mass injection rate $\dot{M}$. The associated thickness of the outflow is $l = c\Delta t$. The entropy in the region where the energy is released is parametrized by a dimensionless parameter $\eta = L/\dot{M}c^2$. Spherical symmetry is assumed, but generalization for anisotropic case with $\eta(\theta)$, where θ is the polar angle is straightforward. When $\eta \gg 1$ the bulk Lorentz factor changes

with the radial distance as

$$\Gamma \simeq \begin{cases} \dfrac{r}{R_0}, & R_0 < r < \eta R_0, \\ \\ \eta \simeq \text{const}, & r > \eta R_0, \end{cases} \tag{1}$$

During both acceleration and coasting phases the continuity equation for the laboratory number density reduces to

$$n = \begin{cases} n_0 \left(\dfrac{R_0}{r}\right)^2, & R(t) < r < R(t) + l, \\ \\ 0, & \text{otherwise}, \end{cases} \tag{2}$$

where $R(t)$ is the radial position of the inner boundary of the outflow.

The optical depth for a spherically symmetric outflow is[27,33]

$$\tau = \int_R^{R+\Delta R} \sigma n \left(1 - \beta \cos\theta\right) \frac{dr}{\cos\theta}, \tag{3}$$

where $R + \Delta R$ is the radial coordinate at which the photon leaves the outflow, and θ is the angle between the velocity vector of the outflow and the direction of propagation of the photon, n is the laboratory number density of electrons and positrons, which may be present due to pair production. The dominant interaction of photons in our case is Compton scattering in the non-relativistic regime, so σ is the Thomson cross section.

Electron-positron-photon plasma with baryon loading reaches thermal equilibrium before its expansion starts.[34,35] With decreasing entropy η opacity due to electrons associated with baryons increases and eventually dominates over pair opacity. For the laboratory density profile (2) one has in the radial direction

$$\tau = \begin{cases} \dfrac{1}{6}\tau_0 \left(\dfrac{R_0}{R}\right)^3, & R_0 \ll R \ll \eta R_0, \\ \\ \dfrac{1}{2\eta^2}\tau_0 \left(\dfrac{R_0}{R}\right), & \eta R_0 \ll R \ll \eta^2 R_0, \\ \\ \tau_0 \left(\dfrac{R_0}{R}\right)^2, & R \gg \eta^2 R_0, \end{cases} \tag{4}$$

where

$$\tau_0 = \frac{\sigma L}{4\pi m_p c^3 R_0 \eta} = n_0 \sigma R_0. \tag{5}$$

The first two lines correspond to a *photon thick outflow* and the third line corresponds to a *photon thin outflow*.[27]

The photospheric radius R_{ph} is defined by equating (4) to unity

$$R_{ph} = \begin{cases} R_0 \left(\frac{\tau_0}{6}\right)^{1/3}, & \tau_0 \ll \eta^3, \\ R_0 \frac{\tau_0}{2\eta^2}, & \eta^3 \ll \tau_0 \ll 4\eta^4 \frac{l}{R_0}, \\ (\tau_0 R_0 l)^{1/2}, & \tau_0 \gg 4\eta^4 \frac{l}{R_0}. \end{cases} \tag{6}$$

In eqs. (4) and (6) the regions of validity of different approximations are expressed either for radius or for parameters of the outflow. The crucial parameter which determines whether the outflow is photon thick or thin is the ratio

$$\chi = \frac{\tau_0}{4\eta^4} \frac{l}{R_0}. \tag{7}$$

The outflow is photon thin for $\chi \gg 1$ and it is photon thick otherwise.

3. Relativistic diffusive photosphere

The definition of the photosphere implies that at this position in space the outflow as a whole becomes transparent to radiation. However, emission emerges from the outflow when it is optically thick as well. Such emission is due to radiative diffusion, which transfers the energy from deeper parts of the outflow towards its surface. Naively one can think that such an effect is negligible in ultrarelativistic outflows. However, this is not the case.[4] Indeed, the comoving time, which photon takes to cross the outflow with comoving thickness $l_c = \Gamma l$ is $t_c = l_c^2/D_c$, where $D_c = c/3\sigma n_c$ is the diffusion coefficient, $n_c = n/\Gamma$ is the comoving density of the outflow. The radial coordinate of the outflow at this time is $R \simeq \Gamma c t_c$.

This diffusion radius is found in Ref. 27, and it is given by

$$R_D = \left(\tau_0 \eta^2 R_0 l^2\right)^{1/3}, \tag{8}$$

where eq. (5) has been used. It turns out to be always smaller than the photospheric radius of photon thin outflow, $R_D \ll R_{ph}$, so the radiation escapes such an outflow before it becomes transparent, just like in the supernova ejecta. In this sense the characteristic radius of the photospheric emission is not the photospheric radius found from (4), but the radius of diffusion (8). The probability distribution of last scattering of photons in diffusive photospheres is qualitatively different from the usual photospheric emission.[26] Besides, the comoving temperature of escaping radiation is different from the temperature at the photospheric radius. Applicability of the photon thin asymptotics, last line in eq. (6), can be written using eq. (8) as

$$l \ll \frac{R_D}{\sqrt{2}\eta^2}. \tag{9}$$

For larger thickness l photon thin asymptotics disappears, so in the limit $l \to \infty$ the stationary wind with photon thick asymptotics is recovered.

Adiabatic expansion implies[36] that the observed temperature of the outflow does not change while it is accelerating, and it decreases as $T_{obs} \propto R^{-2/3}$ at the coasting phase. Taking into account the finite size of emitter and the cosmological redshift z one has[37]

$$T_{obs} = \frac{\xi}{1+z} T_0 \left(\frac{\eta R_0}{R_D} \right)^{2/3}, \tag{10}$$

where ξ is a numerical factor of order unity. In estimates below $\xi = 1.48$ is assumed following Ref. 37, which is found from the Monte Carlo simulations in the infinite wind approximation, though the value of ξ in the acceleration phase and in the photon thin case could be slightly different. The temperature at the base of the outflow is

$$T_0 \simeq \left(\frac{L}{4\pi c a R_0^2} \right)^{1/4}, \tag{11}$$

where $a = 4\sigma_{SB}/c$ is the radiation constant, σ_{SB} is the Stefan-Boltzmann constant. Finally, the duration of photospheric emission for a distant observer is

$$t_a^D = (1+z) \frac{R_D}{2\eta^2 c}. \tag{12}$$

In the photon thick case the duration of thermal emission is determined by the width of the outflow l, which is unconstrained. In the photon thin case this duration is given by eq. (12) and it is a function of the diffusion radius and the Lorentz factor.

The luminosity of photospheric component scales with radius as

$$L_{ph} = L_0 \left(\frac{\eta R_0}{R} \right)^{8/3}, \tag{13}$$

and the applicability condition of the photon thin case in eq. (6) and together with the definition of diffusion radius in eq. (8) imply for the luminosity of diffusive photosphere

$$L_{thin} < L_0 \left(\frac{R_0}{\eta l} \right)^{8/3} \ll L_0. \tag{14}$$

This means that thermal emission is much weaker than the emission of the prompt radiation, if γ-rays are produced with high efficiency there. For $l \sim R_0$ this condition strongly favours small values of η and, consequently, small Lorentz factors of the outflow.

4. Determination of initial radius and bulk Lorentz factor of the outflow

Assuming that the observed thermal component in early afterglows of some GRBs is of photospheric origin, one can estimate initial radius of the outflow directly from

observations.[37] Indeed, in the ultrarelativistic regime one has

$$\mathcal{R} \equiv \left(\frac{F_{obs}^{BB}}{\sigma_{SB} T_{obs}^4} \right)^{1/2} = \zeta \frac{(1+z)^2}{d_L} \frac{R}{\Gamma}, \tag{15}$$

where R is the emission radius, d_L is the luminosity distance, ζ is a numerical factor of order unity. Following Ref. 37 $\zeta = 1.06$ is assumed for the estimates below. In Ref. 37 the emission radius R was associated with the photosphere of the *photon thick* outflows. However, this relation is valid for any ultrarelativistic emitter. Therefore, from eqs. (10), (15) and (11) the initial radius is

$$R_0 = \frac{4^{3/2} d_L}{\xi^6 \zeta^4 (1+z)^2} \mathcal{R} \left(\frac{F_{obs}^{BB}}{Y F_{obs}} \right)^{3/2}. \tag{16}$$

In the derivation of this results only two assumptions are made. First, the outflow should be coasting at ultrarelativistic speed, $\Gamma = \eta \gg 1$. Secondly, the relation $L = 4\pi d_L^2 Y F_{obs}$ is used, where Y is the fraction of the total luminosity L and the energy emitted in X and γ-rays *in the prompt phase*.

In addition to the initial radius R_0 an equation for the Lorentz factor can be obtained. Since the emitter radius for the *photon thin* outflows is the diffusion radius $R = R_D$, from eqs. (8) and (15) one obtains, see also Ref. 38

$$\frac{\eta}{l} = \frac{\zeta^{3/2} (1+z)^3}{d_L^{1/2}} \left(\frac{\sigma Y F_{obs}}{m_p c^3 \mathcal{R}^3} \right)^{1/2}. \tag{17}$$

Therefore, the Lorentz factor can be determined if l is known. In the particular case $l = R_0$ from (17) it follows the minimum Lorentz factor for which the photon thin case applies

$$\eta_{thin} = (1+z) \left(d_L \frac{Y F_{obs} \sigma}{m_p c^3 \mathcal{R}} \right)^{1/2} \frac{4^{3/2}}{\zeta^{5/2} \xi^6} \left(\frac{F_{obs}^{BB}}{Y F_{obs}} \right)^{3/2}. \tag{18}$$

The condition (9) determines the applicability limit of the photon thin case, so for $\sqrt{2}\eta^2 l = R_D$ the photon thick case is recovered[37]

$$\eta_{thick} = \left[\zeta (1+z)^2 d_L \frac{\sigma Y F_{obs}}{m_p c^3 \mathcal{R}} \right]^{1/4}. \tag{19}$$

Equations (17) and (18) allow the determination of the bulk Lorentz factor of the *photon thin* outflow, provided the measurement of the total flux F_{obs} and the parameter $\mathcal{R}$. Comparing eqs. (18) and (19) leads to the conclusion that the Lorentz factor inferred from the photon thin asymptotics is typically smaller than the one of the photon thick case; besides, it contains the inverse of the Y parameter, unlike a factor $Y^{1/4}$ in the latter case.

It is important to stress that from the theoretical point of view, given the total luminosity and the initial radius of the outflow one cannot distinguish between photon thick and photon thin cases as both sets of parameters are possible with different η and photospheric radius. These parameters are related by eq. (15), therefore

independent observational information is required in order to differentiate between the two cases.

5. GRB cocoons

Consider typical parameters relevant for GRB jets which is penetrating the progenitor.[17] In what follows introduce the notation $A_x = A/10^x$, so the luminosity L_{52} stands for 10^{52} erg/s, which is the isotropic luminosity. While the entropy of the jet can take large values, the mixing between the progenitor and the jet lowers the entropy of the cocoon, so $\eta = 10$ is chosen, as a reference value. It is also likely that the entropy is a decreasing function of the angular distance from the jet. Assume that initial radius of the wind R_0 is given by the radius of the core of the progenitor WR star $R_0 \sim 10^9$ cm, and the thickness of the wind corresponds to the size of the WR star $l_{12} = 10^{12}$ cm.[39] The crucial parameter which determines whether the outflow is photon thick or thin is the ratio

$$\chi \simeq 29 L_{52} l_{12}^{-1} \eta_1^{-5}. \tag{20}$$

For $\chi \gg 1$ the outflow is photon thin, which is the case for our fiducial parameters. Considering the extreme dependence on η, for smaller η the condition is clearly satisfied. Hence the cocoon is in the photon thin regime and therefore the radiation from the cocoons is governed by radiative diffusion. The diffusion radius is

$$R_D \simeq 4.9 \times 10^{14} L_{52}^{1/3} \eta_1^{1/3} l_{12}^{2/3} \text{ cm}, \tag{21}$$

and the arrival time corresponding to this radius is

$$t_a^D = (1+z)\frac{R_D}{2\eta^2 c} \simeq 81.7(1+z) L_{52}^{1/3} \eta_1^{-5/3} l_{12}^{2/3} \text{ s}, \tag{22}$$

which is the typical duration of thermal emission observed in early afterglows of GRBs.

The observed temperature at the diffusion radius is

$$T_{obs} = 0.12 L_{52}^{1/36} R_9^{1/6} \eta_1^{4/9} l_{12}^{-4/9} \text{keV}, \tag{23}$$

which is also a typical temperature of thermal emission in early afterglows of GRBs.[13]

Such inferred values of temperature and duration call for closer attention to the radiation properties of photon thin outflows.

6. Case studies

All GRBs reported in Ref. 13 with measured redshifts and thermal component detected in their early afterglows were considered, namely GRBs 060218, 090618, 101219B, 111123A, 111225A, 121211A, 131030A, 150727A, 151027A. Observed temperature, thermal flux and total flux were averaged for the entire duration of the thermal emission. The initial radius was found from eq. (16). Two values of the

Lorentz factor in photon thin, eq. (18), and photon thick, eq. (19), cases were determined. Then the minimum value of the Y parameter is found which allows the duration of the photospheric emission (12) to be not less than the observed duration of the thermal component. Only six cases allow both photon thick and photon thin interpretations for the photosphere; for other cases photon thin case does not apply because eq. (19) gives smaller Lorentz factor than eq. (18).

GRB 060218. This is a well studied nearby GRB[15] with record breaking duration of the thermal signal interpreted as the break out of a shock driven by a mildly relativistic shell into the dense wind surrounding the progenitor, see however Refs. 40, 41. The thermal emission in this burst with observed temperature $T_{BB} = 0.15$ keV may be also explained as a photosphere of a cocoon launched from initial radius 3.18×10^{11} cm with a mildly relativistic Lorentz factor $1.2Y^{-1} < \Gamma < 1.6Y^{1/4}$ emitting in the photon thin regime. This estimate of the Lorentz factor is in agreement with radio observation at 2 days, requiring $\Gamma \sim 2$.[42] Given that the condition $\Gamma \gg 1$ is not satisfied, results of the theory of diffusive ultrarelativistic photospheres can be applied to this case with great care. In particular, the estimated duration of the thermal signal is only $13Y$ s.

GRB 090618. This burst may represent a canonical case of photon thin outflow launched from the initial radius 10^9 cm with the Lorentz factor $3Y^{-1} < \Gamma < 40Y^{1/4}$. Assuming instantaneous energy injection with $l = R_0$ one finds $Y = 5.7$. The duration of the thermal emission with observed temperature about 1 keV is about $6Y$ s. Note that thermal emission has also been claimed in the prompt phase, with a higher temperature ranging from 54 to 12 keV.[43] Such thermal emission in the prompt phase may be interpreted as a photosphere of the photon thick outflow. Indeed, if the initially high entropy η decreases with time the outflow should experience a transition from photon thick to photon thin case.

GRB 111225A. This case is similar to GRB 060218, but with smaller initial radius of 8.3×10^9 cm and Lorentz factor in the range $1 < \Gamma < 6.0Y^{1/4}$. The duration of the thermal emission with observed temperature of 0.18 keV is about $126Y$ s, with $Y = 2.0$ for $l = R_0$. The lower bound on the Lorentz factor in unconstrained. It may correspond to a cocoon emitting in the diffusive photon thin regime.

GRB 131030A. This case is a typical long burst, similar to GRB 090618, it allows Lorentz factors in the photon thin case in the following range: $4.3Y^{-1} < \Gamma < 66Y^{1/4}$. The duration of the thermal emission with observed temperature of 1.12 keV is about $2.0Y$ s. The initial radius is 3.74×10^8 cm. For instantaneous energy injection $Y = 19$.

GRB 150727A. This case is similar to GRB 111225A with initial radius 1.1×10^9 cm and Lorentz factors in the range $1 < \Gamma < 11Y^{1/4}$, allowing for a photon thin interpretation. The duration of the thermal emission with observed temperature of 0.47 keV is about $191Y$ s, with $Y = 2.1$.

GRB 151027A. This case is similar to GRBs 090618 and 131030, however with quite large initial radius 1.5×10^{10} cm and Lorentz factors in the narrow range

$23 < \Gamma < 26 Y^{1/4}$. The duration of the thermal emission with observed temperature of 0.96 keV is about $0.47Y$ s, with $Y = 64$.

7. Discussion

The difference between the present work and the approach followed in Ref. 16 should be emphasized. The main assumption of that work is the presence of unknown dissipation mechanism, which transforms part of the kinetic energy of the outflow into radiation, postulated in Ref. 44. Such dissipation can boost the luminosity of thermal emission and it might be required to explain subdominant thermal component during the prompt emission or even the prompt emission itself, see Ref. 45. Concerning observations of this component in the early afterglow, dissipation is not required, as it is much weaker than the prompt radiation.

Similarly, there is a difference between the present work and the work in Ref. 17. There two regimes of expansion are considered: Newtonian ($v < c$) and ultrarelativistic $\eta \gg 1$. For the latter, which is of interest here, the emission was assumed to originate at the photospheric radius, given by the last line in eq. (6). As discussed in Sec. 3 above, photons in this case diffuse out much earlier, so that no photons are left in the outflow when it arrives to the photospheric radius. For this reason estimations of the luminosity and observed temperature in that paper cannot be used.

Qualitative difference in dependence of observed flux and temperature on time for photon thin outflows determine their observed properties. In particular, since the flux up to diffusion time (22) is almost constant and its luminosity is much weaker than the prompt radiation luminosity, see eq. (14), the thermal component become visible after the steep decrease of observed luminosity following the end of the prompt phase. This is indeed where such thermal component is identified in many GRBs. Its disappearance is naturally explained by diffusion of the radiation kept in the outflow. Hence it implies that no more photons are generated neither in the outflow nor in the central engine.

We show that in several GRBs, namely GRB 060218, 111225A and 150727A, the thermal component observed in the early afterglow may originate from mildly relativistic cocoons emerging from the progenitors together with the jet, due to relatively small values of inferred Lorentz factors $\Gamma < 10$.

Such emission observed in other GRBs such as 090618, 131030A and 151027A correspond to large Lorentz factors $\Gamma > 10$, indicating a jet origin of the photospheric emission. Besides, these results suggest that the progenitors of some long GRBs, in particular GRB 090618 and 131030A could be rather compact objects, with radius $l \sim 10^9$ cm.

It is important to stress that the relatively low temperature of the thermal component observed in the early afterglow with $T \sim 0.1 - 10$ keV, in contrast with typical temperatures detected during the prompt emission with $T \sim 10 - 100$ keV does not indicate small Lorentz factor of the outflow. Conversely, it may point to

photospheric origin of the thermal emission in the photon thin regime. Instead, large Lorentz factors $\Gamma \gg 1$ assumed in the model imply small mass of the emitting plasma, which is consistent with the cocoon interpretation.[17]

Notice that possible presence of thermal components both in the prompts radiation and in the early afterglow, as well as the presence of breaks in temperature dependence on time found in many cases[46–48] may correspond to the transition from photon thick to photon thin asymptotics in hydrodynamic evolution of the outflow powering GRBs.

In this work the theory of diffusive emission from relativistic photospheres is confronted with observational data on a sample of GRBs with thermal component in the early afterglows. The measurement of temperature and flux of the thermal component along with the total flux in the prompt phase are used to determine initial radii of the outflows as well as their Lorentz factors. The results indicate that in several cases (GRBs 060218, 111225A and 150727A) the inferred Lorentz factors are relatively small, $\Gamma < 10$, while in other cases (GRBs 090618, 131030A and 151027A) the inferred Lorentz factors are larger, $\Gamma > 10$. Such differences suggest two possible sources of the thermal component: mildly relativistic cocoons or highly relativistic jets. Results obtained above are valid only for those cases, where inferred Lorentz factor is relatively small, below few tens. For other cases identified in Ref. 13 inferred Lorentz factors are larger, and photon thin interpretation does not apply.

These results are the first indication that radiative diffusion may play an important role not only in nonrelativistic outflows, but also in ultrarelativistic outflows, represented by GRBs.

In this proceedings, we give a brief general overview of the parallel session on photospheric emission in gamma-ray bursts (GRBs), which took place during the online 16$^{\text{th}}$ Marcel Grossmann Meeting. The session covered theoretical and observational aspects of photospheric emission. In particular, spectral, temporal and polarization properties were discussed.

Keywords: Gamma-ray bursts, Photospheric emission, Thermal emission, Non-thermal emission, Jet simulations.

1. State of the art

Photospheric emission models are seen as prime contenders to explain the prompt phase of gamma-ray bursts, see *e.g.*[1] for a review. This emission is produced when the expanding jet becomes optically thin to Compton scattering,[2] which is the dominant interaction mode for photon of comoving energy $\sim$ 1keV. Photospheric emission is a naturally expected process in the widely discussed fireball model.[3–6] It can be highly efficient if the transparency takes place at small radius, that is to say close to the transition radius between accelerating and coasting phase,[3,7–9] and it naturally predicts a clustering of the spectral peak energy around 500 keV.[10]

It has long been known that photospheric models in their simplest flavors fail to explain the shallow low energy spectral slope seen in most GRBs.[11–15] This picture changed in the past 15 years when it was realized that the spectra produced at the photosphere can be highly non-thermal due to 1- energy dissipation below the photosphere either via shocks,[16–18] magnetic reconnection[19–22] or neutron decay,[23] and 2- geometrical effects due to the structure of the jets[24,25] and the photon last scattering position.[11,14,23]

The aforementioned effects are difficult to study analytically, as any analysis depends on ad hoc assumptions on the geometry of the jet, dissipation mechanisms and their localization. In recent years, 3D (GR) MHD simulations coupled to Monte-Carlo radiative transfer calculations were designed to study photospheric emission

in the context of GRBs solve those opens issues.[26–33] One of the most interesting finding is that the luminosity drop for off-axis observers is limited by the structure of the jet.

Moreover, the simulations were successful in reproducing correlations between observer position, luminosity, peak energy, and observed polarization. In particular, several important successes were obtained in explaining the Amati correlation[34] (between the isotropic total energy $E_{\rm iso}$ and the peak energy $E_{\rm p}$), the Yonetoku correlation[35] (between the isotropic luminosity $L_{\rm iso}$ and $E_{\rm p}$) and the Goletneskii relation[36] (between the luminosity and $E_{\rm p}$) by considering a distribution of off-axis observers.

Finally, the simulations permitted to obtain detailed polarization predictions. In particular, it was found from numerical simulations of photon propagation inside a jet that a high degree of time-resolved polarization requires off-axis observers, while the polarization for on-axis observers is lower.[37–39] Using a semi-analytical jet model, it was found that the polarization degree correlates to a substantial drop in luminosity.[37,40] Instead, recent hydrodynamical simulations[38,39] showed that the drop in luminosity for observer angles might be smaller than expected thanks to emission from the jet cocoon. Extending the analysis to lower frequencies it was shown that the polarization degree is larger at low energies, either thanks to the effect of synchrotron emission[41] or due to higher scattering angle towards the observer.[39]

Despite these many successes, the correlation analysis is limited to a few initial setups because of the large resources needed for each independent simulations and their post-processing analysis. In the forthcoming years, the reliability of the already obtained correlation results will be tested and refined against many more runs with different initial conditions and methods. In addition, the simulations are not yet mature enough to produce detailed spectral predictions, which could be confronted to observed data.

Concerning the spectral analysis in the context of photospheric emission, two different paths were explored in the past few years. First, detailed time-resolved spectral analysis of GBM data from many bursts were performed.[42–44] Specifically, the spectra were fitted with a cut-off power-law and the obtained low energy slope distribution were carefully investigated. It was realized that many bursts have one to several time bins with spectra harder than the limits from the synchrotron line of death. These studies concluded that photospheric emission should be the mechanism at work in those bursts, textbfsee however[45].

Second, simplified photospheric models, such as the DREAM model,[46,47] were directly fitted to observed GBM spectra[48] finding 1- good agreement for the bursts with the hardest low energy slope when considering the photospheric emission taking place at the transition between accelerating and coasting phase, and 2- good overall agreement with other bright bursts, when considering localized energy dissipation. It is expected that those studies will be extended to larger sample and refined models in the near future.

2. Talks at the session

The session was run in two blocks of three hours.

Asaf Pe'er delivered a review talk "Understanding prompt emission: where do we stand?" where he summarized basic observational information about the prompt emission and problems originating from misconceptions which are related to usage of models (including the progenitor, jet launching, dynamics and dissipation), the nature and dynamics of the outflow (e.g. baryonic vs. magnetic) and the radiation mechanisms (e.g. photospheric vs. synchrotron). He also discussed the spectral and polarization properties of non-dissipative photospheric emission, and its ability to explain observed correlation. Finally, he mentioned a new model of the prompt emission based on backscattering of the seed photons on a cold relativistic cork which appears natually in front of the jet in many progenitor models.

Ore Gottlieb presented a talk "Probing the jet launching mechanism from prompt emission of GRBs" where he described the ways to infer the information on the jet launching mechanism and its dynamics from the comparison of observations with numerical simulations of jet propagation and its the photospheric emission, focusing specifically on the role of magnetization of the jet. In particular, based on numerical hydrodynamic simulations, including self-consistent simulations within the collapsar model, he discussed and ability to produce jet tilt, intermittency, position of the magnetic dissipation region, and the role of different progenitors in jet launching and cocoon formation.

Gregory Vereshchagin reported a study "Diffusive photospheres in gamma-ray bursts" describing the results of the application of the theory of photospheric emission to the thermal radiation, detected in the early afterglows of some gamma-ray bursts. The inferred Lorentz factors of the outflow are clustered in two groups: few hundreds, indicating classical photospheric emission from ultrarelativistic outflow, and few tens, indicating diffusive regime of the photospheric emission, possibly from jet cocoons.

Tyler Parsotan delivered a talk "Monte Carlo Simulations of Photospheric Emission in Gamma Ray Bursts" in which he described the MCRaT code and its coupling to relativistic hydrodynamical simulations in order to obtain mock observations. He discussed how his code allows him to obtain predictions of the photospheric model, in particular prediction about optical prompt percursors of gamma-ray bursts.

Hirotaka Ito presented results on "Numerical simulations of photospheric emission in GRBs" focusing on the jet structure and its consequences for spectral shapes, polarization signal and correlations between observed quantities, based on hydrodynamical simulations and post processing with the radiative transport.

Yan-Zhi Meng reported the talk "Photosphere emission spectrum of hybrid relativistic outflow for gamma-ray bursts", considering both impulsive injection and continuous wind cases.

J. Michael Burgess in his talk "Spectroscopy of GRBs: Where are we now?" discussed how fitting physical models, instead of phenomenological ones, is important

in order to infer physical information from observations. He mentioned several "myths" about the synchrotron emission model such as the line-of-death and width problem and showed how proper folding through the response function of the instruments demonstrates viability of this model.

Hüsne Dereli-Bégué presented a talk "Classification of Photospheric Emission in sGRBs" where she discussed the fit of a large sample of short GRBs with a phenomenological model based on a non-dissipative photosphere model. The main conclusions are that nearly one third of the spectra are consistent with purely thermal emission, and that a large fraction of bursts may come from subphotospheric dissipation.

Björn Ahlgren discussed "Subphotospheric dissipation evaluated using joint Fermi-Swift observations" and pointed out the importance of using XRT data in addition to the BAT data from the SWIFT satellite, in order to distinguish between photospheric and synchrotron mechanisms of emission in the context of fitting of dissipative photospheric model to the data, focusing specifically on the DREAM model.

Liang Li reported on "Bayesian Time-resolved Spectroscopy of Multipulse GRBs: Variations of Emission Properties among Pulses" where he discussed construction of the catalogue of multipulse bursts, the fitting procedure and the outcomes. In particular, he discussed different trends and correlations between observed quantities such as $F - \alpha$ and $F - E_p$.

The outcome of the discussion with participation of Gregory Vereshchagin, Pe'er Asaf, J. Michael Burgess and Damien Begue is that generally speaking about gamma-ray bursts, despite strong progress both in theory and in observations there are still many unresolved issues such as the origin of the jet, the mechanism of energy dissipation, and the nature of observed variability.

The field is observationally driven, with new recent observational results such as the "anomalous" X-ray behavior of GRB 170817A and the detection of very high energy emission from several sources such as GRB 190114C. However, there are some key observational results, which still need explanation from the theory, in particular the strong spectral evolution within each pulse, the power-law decay of the peak energy, the time evolution of the temperature and so on. From the observational viewpoint, one of the most promising direction is the study of polarization of gamma-ray bursts.

3. Conclusions

To conclude, many critical progresses were made and problem addressed in the past few years. In particular, theoretical and numerical predictions start to be mature enough to allow direct comparison to observations, either via direct spectral fitting or via comparison to the global population parameters. It is expected that this trend will continue, allowing for a refinement of the photospheric emission theories, a better understanding of the data and of gamma-ray bursts.

Gamma-Ray Bursts (GRBs) are energetic transients originating in a violent explosion of a massive star or merger of two compact objects in a binary system. These explosions create a relativistic blastwave which inevitably collides with the circumburst medium and results in external shocks. The emission produced thereby is the afterglow observed in GRBs after the initial prompt phase. The properties of the emitting region, i.e., non-thermal particle spectrum, magnetic amplification, and micro-physical parameters, etc., can be probed by monitoring and modelling the afterglow radiation. The recent detection of very high energy (VHE, > 100 GeV) gamma rays from GRBs has opened a possibility to test theoretical models such as the synchrotron self-Compton (SSC) in GRBs till late times in the afterglow phase. We find that the SSC model explains the afterglow observations of MAGIC-detected GRB 190114C and H.E.S.S.-detected GRB 180720B.

Keywords: GRBs: VHE Components, Afterglow Emission.

1. Introduction

GRBs, one of the brightest electromagnetic events in the universe, are produced in cataclysmic astrophysical events like the collapse of a massive star or mergers of compact binary stars (a neutron star – neutron star or a neutron star and a black hole system).[1,2] The initial prompt burst of the energy is primarily in gamma-rays, and its origin though still debated is linked to the energy released from the central source which is dissipated at the internal shocks or emitted at the photosphere.[3–6] Afterglow emission follows once the prompt emission phase ends in GRBs. The afterglow of GRBs is important to understand the circumburst environment, jet parameters, geometry of the jet and the central engine. Recently, a VHE component is discovered by the ground-based MAGIC telescopes[7–9] and H.E.S.S. telescopes.[10,11] This was anticipated based on the standard afterglow models and its origin was postulated via the inverse Compton scattering of the synchrotron radiation (synchrotron self-Compton).[12–22] Comparatively, other radiation channels like proton

synchrotron require acceleration of protons up to 10^{21} eV and currently are considered less favorable.[23] However, for a combination of afterglow parameters, proton synchrotron can dominate compared to electron synchrotron emission as discussed in the literature.[20,24]

Synchrotron radiation from a decelerating blastwave can explain the multiwavelength afterglow emission from radio to gamma-rays observed in GRBs. The maximum energy detected in GRB 190114C by the MAGIC telescopes and in GRB 180720B by the H.E.S.S. telescopes is higher than the maximum energy that can be produced by synchrotron mechanism, and therefore, self-Compton of these synchrotron photons in the GRB blastwave is invoked to explain these energetic photons.[21]

In this work, we discuss GRB afterglow model and provide multiwavelength modeling of the observations of GRB 180720B and GRB 190114C (Section 2). We summarize our results in Section 3.

2. GRB blast-wave expansion and afterglow radiation

We consider the synchrotron radiation from the electrons accelerated to relativistic energies in the forward shock. Further, these synchrotron photons are upscattered by the same population of relativistic electrons. We revisit the synchrotron self-Compton model by[21] and the details of the expressions used here are taken from the SSC formalism for GRBs.[25]

Table 1. Afterglow model parameters used for the interpretation of multiwavelength observation of GRB 180720B and GRB 190114C. The VHE component detection time information $t_{\rm VHE,obs}$ is taken from[10] for GRB 180720B and from[7,8] for GRB 190114C respectively.

Parameters	GRB 180720B	GRB 190114C
$t_{\rm VHE,obs}$(s)	$> 3.6 \times 10^4$	> 55
$E_{k,\rm iso}$(erg)	4.5×10^{54}	$4 \times 10^{54}(1 \times 10^{53})$
Γ	400	300(36)
$t_{\rm dec}$(s)	69	$52.6(2.3 \times 10^4)$
$t_{0,\rm SSC}$(s)	6×10^{-6}	8.5(61)
$A_\star$		0.02(0.02)
n_0(cm^{-3})	0.035	
p	2.4	2.18(2.5)
ϵ_e	0.05	0.03(0.08)
ϵ_B	1.2×10^{-5}	0.01(0.07)
ϕ	1	1 (1)

2.1. *GRB 190114C multiwavelength emission*

GRB 190114C was located at a redshift $z = 0.4245 \pm 0.005$[27] and its prompt gamma-ray emission releases isotropic energy $\sim 3 \times 10^{53}$ erg.[26] The very high energy gamma-ray detection from GRB 190114C was reported by MAGIC telescope.[26,28]

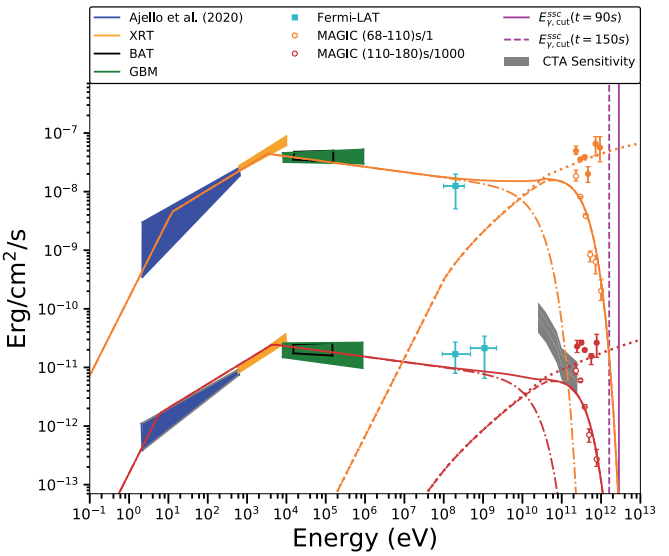

Fig. 1. SED for GRB 190114C reproduced from our earlier work,[25] with slightly different values of input model parameters. The data is extracted from.[26]

This source was observed in multiwavelengths (radio to gamma rays) by 6 satellites and 15 ground based telescopes.[26] We modelled GRB 190114C SEDs and light curves simultaneously and found that in late time the optical emission appears to be harder, which cannot be accounted for by the contribution from the host galaxy. Refreshed shocks are slow shells that will catch up with the afterglow shock region at late times.[29,30] This will enhance the energy of the forward shock medium and can be useful to explain the optical hardness seen in case of GRB 190114C. The flux below the cooling frequency due to refershed shock emission is $((1 + f^{(3+p)/4}))F_{\rm Sy}$, where $F_{\rm Sy}$ is the synchrotron flux due to the forward moving shell and $f = 5$ is the amount of higher flux compared to the optical emission of forward moving shell. The flux above the cooling frequency due to refershed shock emission is $((1 + f^{(2+p)/4}))F_{\rm Sy}$.

In our Fig. 2 we have included the contribution due to a refershed shock which can explain the late time optical flux and at the same time won't exceed the flux in X-rays. The late time onset of the afterglow constrains the initial Lorentz factor value of the slow moving shell to be ~ 36. The SSC emission is considered in the Thomson scattering regime (for details, see[25]). The Compton parameter is approximately constant and $Y \sim t_2^{-0.1}$, also shown in Figure 5.

2.2. *GRB 180720B multiwavelength emission*

GRB 180720B was located at a redshift $z = 0.653$[31] and its prompt gamma ray emission releases isotropic energy $\sim 6 \times 10^{53}$ erg.[10] In case of GRB 180720B, VHE

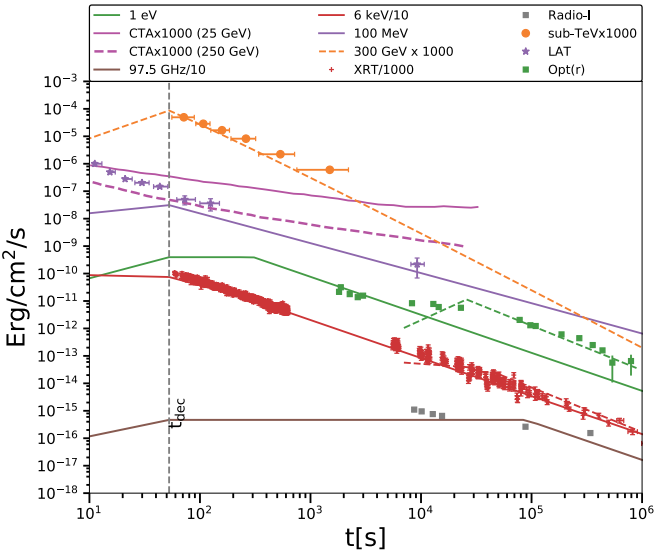

Fig. 2. Light Curves for GRB 190114C where the late time optical emission is explained via refreshed shock scenario. The data used here is extracted from[26] and Swift XRT database, https://www.swift.ac.uk/analysis/xrt/.

gamma-rays were detected by the H.E.S.S. telescopes after 10 hours.[32] Due to this late time detection we find that the emission of sub-TeV photons falls in the Klein Nishina (KN) regime, the medium is thin to pair production of VHE gamma rays, and we utilize the KN feedback effects on the cooling of electrons based on the formalism discussed by.[33] A comparison of Compton parameter is shown in Figure 5 for Thomson and KN cases. The afterglow model explains the data well as shown in Figures 3 and 4, where the SED and light curves are plotted for same set of input parameters. The model predicts higher levels of optical emission and we need to consider the absorption effects which lowers the optical flux by a factor of 0.5. The model parameters used in our work are shown in Table 1.

3. Summary and Conclusion

The VHE gamma-ray observations of two GRBs studied here are well explained using the synchrotron and SSC models. The late time optical afterglow for these two objects are in contrast to each other. In GRB 190114C the optical emission is harder and we required a refreshed shock to explain it, however for GRB 180720B the model produces higher level of optical flux by a factor of 0.5. Hence there is absorption of optical flux in the host Galaxy of GRB 180720B. The absorption of VHE photons for pair-production, in the blastwave, is negligible. The extra-galactic background light (EBL) absorption are considered for finding the maximum energy of the photons based on the model by.[34] These cut-off effects are important above

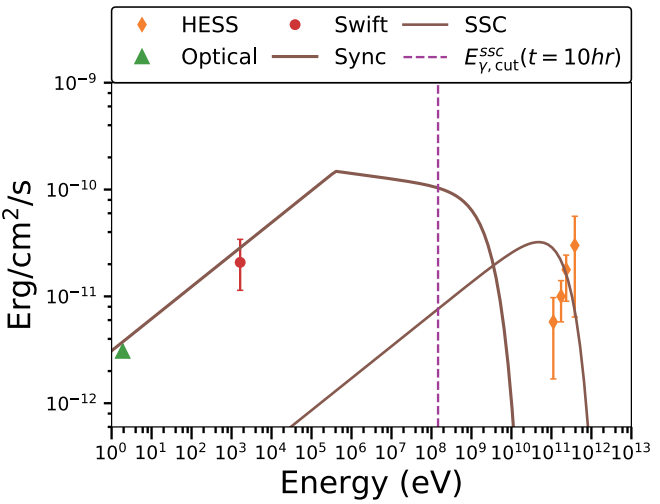

Fig. 3. SED for GRB 180720B using SSC model plotted against the HESS onservations[10] at duration 10 hr.

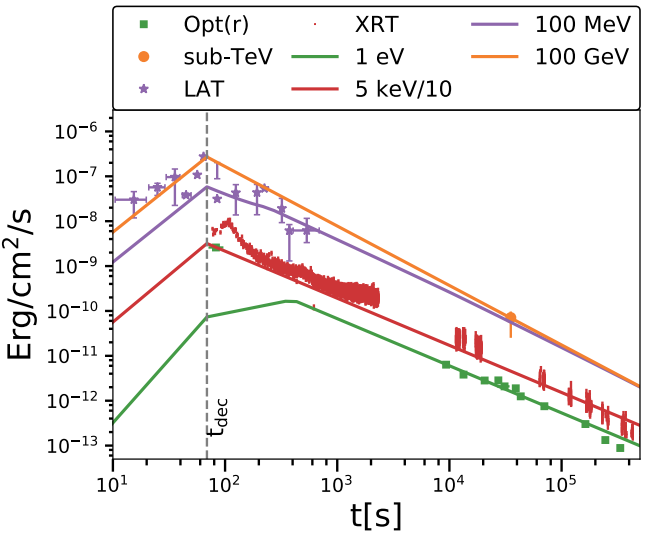

Fig. 4. Light Curves for GRB 180720B, the data used here is extracted from[10] and Swift XRT database, https://www.swift.ac.uk/analysis/xrt/.

200 GeV and 160 GeV for GRB 190114C and GRB 180720B respectively. The t^2 dependence for the blastwave flux before deceleration is used for both the ism and wind media since the flux dominates due to the area of the blastwave expansion. The bulk Lorentz factor Γ and $E_{k,\mathrm{iso}}$ and ϵ_e have approximately similar values for

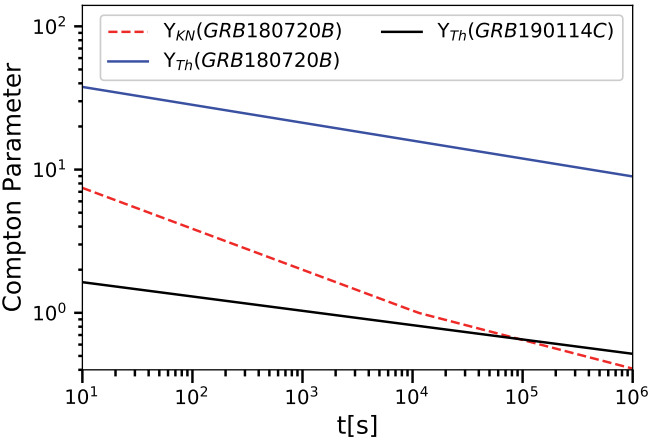

Fig. 5. Compton parameter Y estimated for two GRBs. We have modelled GRB 190114C using Thomson approximation, however for GRB 180720B we required SSC in KN regime.

both GRBs, however the fraction of energy in the magnetic field ϵ_B is very low in GRB 180720 B. This low value of ϵ_B is also reported in the SSC modelling of this source in other works.[35] Also for GRB 180720B we find the ISM medium is more suitable for modelling, which is consistent with the X-ray afterglow observations.[36]

The VERITAS gamma-ray burst follow-up program

D. Ribeiro* for the VERITAS Collaboration†

Physics Department, Columbia University,
New York, NY 10027, USA
**E-mail: dr2792@columbia.edu*

Recent detections of gamma-ray bursts (GRBs) at energies above 100 GeV demonstrate that imaging atmospheric Cherenkov telescopes (IACTs) operating in the very-high-energy range (VHE; E > 100 GeV) can provide insights into the physics of GRBs. By searching for the highest-energy photons emitted by GRBs, these telescopes can help answer questions about the particle acceleration and emission processes that occur during both the prompt and afterglow phases of GRBs. VERITAS is a very-high-energy IACT array located at the Whipple Observatory in southern Arizona, which has maintained an active GRB observing program since mid-2006. In this presentation, we will share some of the recent achievements of the VERITAS GRB follow-up program. We will discuss the development of analysis methods tailored to transient signals, and how the upper limits on the VHE emission obtained from observations of prominent bursts by VERITAS allowed us to constrain radiation mechanisms in the afterglow (e.g., for GRB 130427A) and constrain properties of the environment in which the burst took place (e.g., for GRB 150323A). Compact binary mergers that trigger short GRBs may also result in gravitational wave emission, so we will review both our follow-up program from LIGO/Virgo triggers, and also the use of archival VERITAS data to search for short GRBs based on sub-threshold events for LIGO/Virgo. Lastly, based on the properties of the VHE-detected GRBs, we will discuss recent changes to our follow-up strategy to account for the *Swift*/XRT properties for optimal VERITAS observing sensitivity.

Keywords: Gamma-ray bursts, GRBs, gravitational waves

1. Introduction

Gamma-ray bursts (GRBs) are a class of astrophysical explosions that are some of the brightest events in the universe. Emitting total energies greater than 10^{53} erg/s, these events are detected in the optical, X-ray and high-energy (HE) to very-high-energy (VHE) gamma-rays. The physical mechanisms to explain the source of the high-energy emission range from synchrotron to synchrotron-self-Compton (SSC) processes based on the environment of the GRB emission regions. Particularly important are the highest energy photons in the VHE range that can constrain the properties of the GRB emission. Ground-based gamma-ray telescopes are well suited to these observations, and the recent detections of photons above 100 GeV by H.E.S.S. and MAGIC provide insights into the physics of GRBs[1–5]

In this paper, the VERITAS GRB follow-up program is discussed. Section 2, describes the VERITAS instrument and observation capabilities. In Section 3, the

†`https://veritas.sao.arizona.edu`

GRB observations by VERITAS are summarized. In Section 4, the techniques used to improve future observations and optimize data analyses are described. Section 5 describes how the VERITAS GRB follow-up program is enhanced by the new gravitational wave trigger with the start of operation of the LIGO/Virgo gravitational wave (GW) observatory.

2. VERITAS

The Very Energetic Radiation Imaging Telescope Array System (VERITAS) is a ground-based imaging atmospheric Cherenkov telescope (IACT) array located in southern Arizona, USA. VERITAS consists of four 12-m IACTs, each equipped with a 499 photo-multiplier tube (PMT) camera and 350 hexagonal mirror facets arranged in a Davies-Cotton optical design.[6] This system enables the detection of air showers formed in the atmosphere by the cascade of particles created from the interaction of the original gamma-ray photon and molecules in the atmosphere.

VERITAS is sensitive to gamma rays of energy 100 GeV to 30 TeV. The mechanical structure of each IACT is capable of a maximum slew speed of 1 degree per second. Each camera has a field of view of 3.5 degrees. VERITAS has a 68% containment radius less than 0.1 degree at 1 TeV.[7] The recorded data is analyzed by two independent pipelines (to enable cross-checking) to reliably select gamma-ray and cosmic-ray events from the camera images, determine energy, angular direction and arrival time of the original photon, and reconstruct a skymap of the observed region.[8,9]

In the scale of short timescale events such as GRBs and other astrophysical transients, the sensitivity is statistics dependent: by one widely required standard, the detection criterion is achieved when observing a minimum number of signal counts ($N_s = 10$), the signal above the background is at least five times the systematic uncertainty in the background estimation, assumed to be 1%, and the Li & Ma statistical significance is 5σ or more.[10] These requirements weaken the achievable flux sensitivity at very short observation times ≤ 100 seconds, particularly for higher energy photons under the assumed power law spectral model, compared to longer term observation campaigns of steady sources.[11] In Figure 1, the relative short timescale sensitivities are shown for *Fermi*-LAT, VERITAS, MAGIC, H.E.S.S. and the future CTA observatories. For a Crab Nebula-like point source detection, VERITAS is capable of a 5σ detection in about 2 minutes.

3. Summary of Observations

VERITAS has followed up on more than 200 GRBs since the beginning of its GRB follow-up program in 2006. The Gamma-ray Coordinates Network (GCN) provides real-time coordinates (via *Notices*) and follow-up reports (via *Circulars*). VERITAS is subscribed to this system and has integrated an automated tracking response for incoming GCN notices. Alerts are quickly parsed and reviewed by on-site observers,

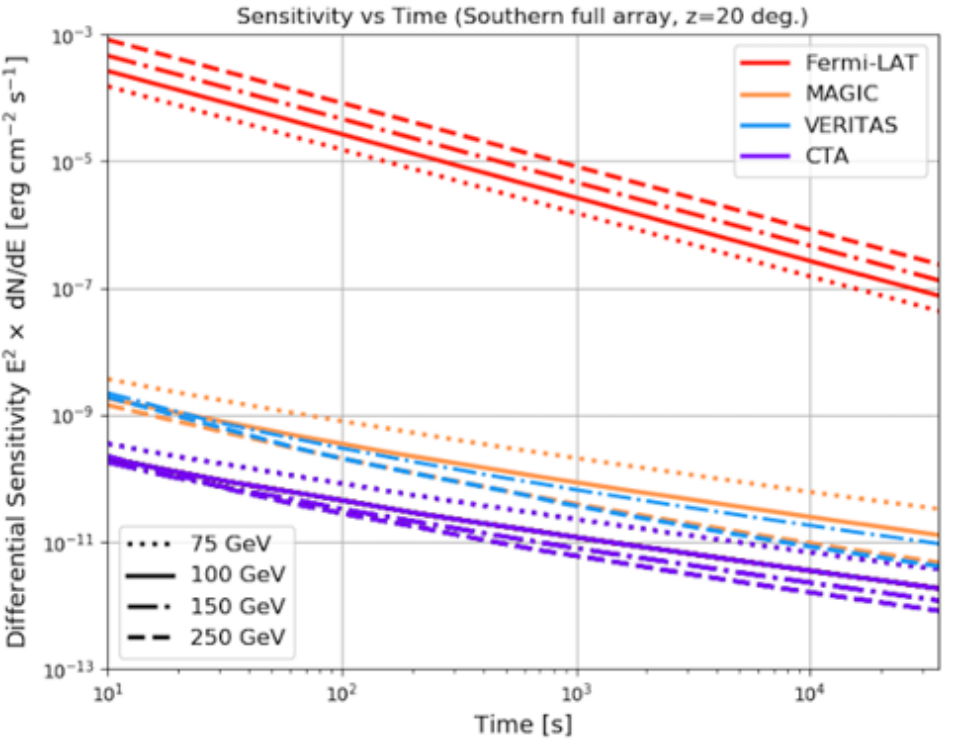

Fig. 1. The short timescale differential sensitivity of various gamma-ray observatories to Crab-like point sources (from[11]). The assumed spectral model is a power law with spectral index of -2.5. Four differential energy bins between 75 and 250 GeV are selected due to the relative overlap between the each observatory's operational energy ranges.

who assess visibility (i.e. checking for observable conditions such as pointing direction, slew time, and weather) and decide whether to follow up with a user-friendly pop-up GUI.

The distribution of the sources of GRB triggers observed is shown in Figure 2. *Swift* and *Fermi*-GBM dominate the alerts with their surveying-mode monitoring systems. Figure 3 shows the frequency of *Swift* (3a) and *Fermi*-LAT (3b) observed bursts since the beginning of the VERITAS GRB program. While *Swift* bursts are significantly more common, *Fermi*-LAT events are prioritized due to their high energy components and a few *Fermi*-LAT bursts are observed every season.

The standard protocol for observing is as follows: if the alert came from *Swift*-BAT, *Swift*-XRT or *Fermi*-LAT, observe up to trigger time plus 3 hours (for a maximum of 3 hours); if the alert came from *Fermi*-GBM only and the burst position is determined to $\leq 5^{\circ}$, observe up to the trigger time plus 1 hour (for a maximum of 1 hour). This protocol prioritizes well-localized and high-probability candidate GRBs. In some extreme cases, exceptions have been made from this protocol, such as GRB 130427A discussed in section 3.1. Figure 4 shows the distribution of delay

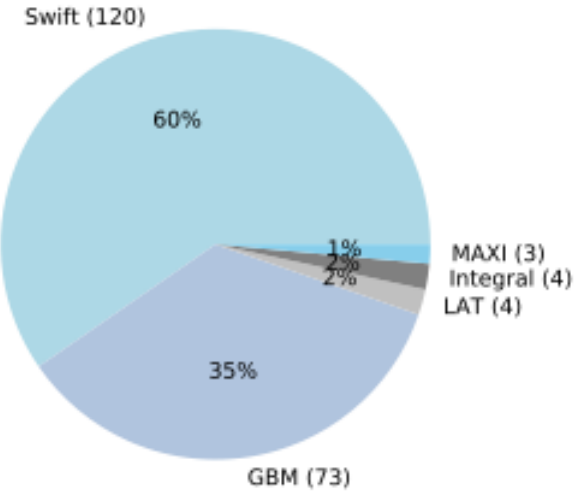

Fig. 2. Distribution of the source of trigger alerts for VERITAS followed-up GRBs.

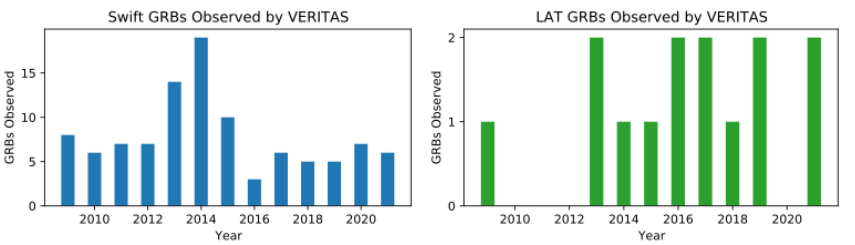

(a) (b)

Fig. 3. Distribution of *Swift* (a) and *Fermi*-LAT (b) observed GRBs since 2009.

times: most have been observations beginning between 10^2 and 10^4 seconds after the burst detections, while a handful of exceptions were made for bright bursts with observations starting $\geq 2 \times 10^4$ seconds.

In the subsections below, three exceptional GRBs followed by VERITAS are discussed, GRB 130427A, GRB 150323A and GRB 190114C.

3.1. *GRB 130427A*

GRB 130427A was a *Fermi*-LAT-detected GRB that was bright enough for VERITAS to follow up almost 20 hours after the burst, yielding meaningful upper limits for the VHE acceleration mechanism.[12] Originally detected by *Fermi*-GBM and *Swift*-BAT, the burst was later associated with a Type Ic supernova (SN2013cq) at redshift of z=0.34.[13] The *Fermi*-LAT spectrum is consistent with a powerlaw spectral model with index of -2.2 up to 20 ks, while the later VERITAS upper

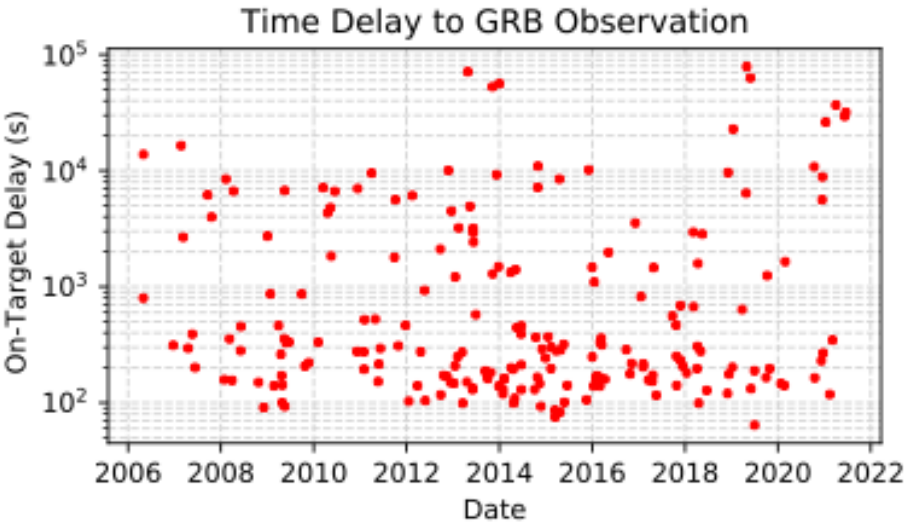

Fig. 4. Delay between the GRB trigger time and the beginning of observations by VERITAS. Most observations were followed up within 3 hours of the alert, while a few exceptionally-bright events were followed up by as much as 20 hours later. The fastest follow-up was ≈ 1 minute after the alert.

limit was calculated assuming a power law model with index -2 (see table 1). The *Fermi*-LAT light curve evolved with a temporal power-law with index of -1.4 ($dN/dt \propto t^{-1.35\pm0.08}$). GRB 130427A is one of the brightest bursts ever followed up by VERITAS.

Table 1. The VERITAS observation of GRB 130427A from (from[14]).

Day	$\mathbf{N}_{on}$	$\mathbf{N}_{off}$	α^{a}	σ^{b}	**UL** erg cm^{-2} s^{-1}
1	165	1164	0.125	1.3	9.4×10^{-12}
2	322	2120	0.143	1.1	6.6×10^{-12}
3	402	2820	0.147	-0.5	2.7×10^{-12}
Total	889	6104	0.141	0.9	3.3×10^{-12}

Note: [a] Relative ratio of exposures of On and Off observing regions.
[b] Li & Ma (1983) test statistic.[10]

Both synchrotron and SSC models proposed to explain high-energy and very-high-energy emission are constrained by the VERITAS VHE upper limit. In the synchrotron model, the VERITAS upper limit can constrain the magnetic field of an assumed interstellar medium (ISM), $B_{ISM} \leq 5\mu\text{G}\ E_{53}^{1/8}\varepsilon_{B,-4}^{1/2}n_0^{3/8}(t/t_V)^{-3/8}$ where the terms are explained in[14] (see[14,15]). In the SSC model, the VERITAS upper limit

constrains the synchrotron emission of the electron population within the emission region, limiting the Klein-Nishina energy to $E_{\rm KN} < 120$ GeV as determined by *Fermi*-LAT temporal data. However, for lower $E_{\rm KN}$, the VERITAS upper limit does not constrain the SSC model, and combined with the single zone interpretation from the early afterglow data, the synchrotron model is preferred.

3.2. *GRB 150323A*

GRB 150423A was a *Swift*-BAT-detected GRB that was observed with the standard follow-up protocol within 270 seconds of the prompt emission peak and at a relatively low redshift of $z = 0.6$. Although not necessarily noteworthy by other observatories, this burst was selected because it had one of the highest observation flux weights compared to other bursts observed by VERITAS.[16]

The derived observational weight combines the extragalactic background light (EBL) absorption factor for each burst with the time delay between burst explosion T_0 and VERITAS observation start time. The EBL absorption is defined by the burst redshift and photon energy ($e^{-\tau(z,E)}$), where the energy is chosen to be the telescope energy threshold, which is a strong function of the telescope elevation angle. The weight can be interpreted as being proportional to the approximate flux of the burst at the time of the observation, where the burst is assumed to have a temporal dependence of $1/t$.

VERITAS began the observation about 2 min after the BAT emission peak. The observation significance is 0.36σ, and with the limited EBL attenuation (only 50% at 100-200 GeV), the upper limit is $< 1\%$ of the prompt fluence. The differential upper limit (99% C.L.) at 140 GeV is 3.7×10^{-10} TeV^{-1} cm^{-2} s^{-1}, while the integral upper limit from 140 GeV to 30 TeV is 1.6×10^{-11} cm^{-2} s^{-1}. The strong upper limit on VHE emission favors an explosion into the stellar wind of a dense progenitor (Wolf-Rayet star), or a weak blast wave in a tenuous ISM.[17]

3.3. *GRB 190114c*

VERITAS also followed up the first IACT-detected GRB 190114C, observed by the MAGIC telescope[a].[1,2,18] VERITAS received the alert during daytime (UT 20:57:04) and waited for the object to rise before beginning observations several hours later. Due to moonlight, the VERITAS cameras were operating with reduced high voltage, which decreases the sensitivity to low-energy gamma-ray events. The low elevation of the burst location ($\leq 32^\circ$) during the observation further impacts the energy threshold. Additionally, clouds occluded the field of view leading to lost data through the observation. Due to these unique observation conditions, VERITAS is currently working toward a calibrated analysis pipeline custom to the challenges of this burst.

4. Optimizations

The observation of the prompt and afterglow emission of GRBs is a primary goal of the VERITAS follow-up program. However, due to the combination of observation conditions such as weather, moonlight, and pointing direction, with the variation of GRB flux and redshift, a significant GRB detection by VERITAS in the VHE range has remained elusive. In light of the probabilistic challenges associated with observing a bright, nearby GRB shortly after a trigger is announced, the following optimization strategies are employed: section 4.1 describes a strategy to monitor and follow-up certain bright *Swift*-XRT GRB candidates, and section 4.2 describes an offline analysis method to incorporate the time dependence of the GRB light curve into the calculation of the significance of excess photon counts.

4.1. Swift *Monitored Triggers*

Some GRBs have bright, extended afterglows in the X-ray band. These bursts may also be bright in the VHE band. Table 2 shows several VHE-detected GRBs and their inferred *Swift*-XRT X-ray flux at the time of detection (along with the corresponding delay between T_0 and the start of the observation). Using these H.E.S.S. and MAGIC detected afterglows, it is prudent to use the *Swift*-XRT inferred flux as a guide for following up on bursts that are more likely to be seen in the VHE band.

VERITAS might be missing some of the bright afterglows for GRBs that become observable at $T > T_0 + 3$ hrs, and therefore we have modified the standard GRB follow-up protocol to include the *Swift*-XRT flux (if available) to adjust the amount of time allocated for each burst. If a *Swift*-XRT flux is available, the spectrum is extrapolated to the VHE range and the light curve is extrapolated for the remainder of the observing window. GRBs with inferred fluxes $> 10^{-11}$ erg cm^{-2} s^{-1} in the X-ray band are observed for as long as they are still above that threshold. Bursts that might have been missed after passing the $T > T_0 + 3$ cutoff can now remain candidates if the X-ray band is still bright. The remaining alerts without a *Swift*-XRT counterpart follow the standard protocol. This selection threshold prioritizes bright events, increasing our probability of detecting VHE events.

4.2. *Time Dependence*

In the conventional analysis of sources observed by IACTs, background and signal regions are determined a priori so that an excess count can be calculated that characterizes the source count rate during an observation period. Following the criteria established, the statistical significance is calculated using Eq. 17 of Li & Ma.[10] However, in this formulation, both the source and background rates are assumed to be time independent. In the case of GRBs and other strongly time-dependent sources, the excess counts may be dominant in certain time bins within the observation and negligible in others, such that the excess counts summed over all time bins are not significant.

Table 2. VHE detected GRBs, as well as the bright GRB130427A, and their inferred XRT flux at the time of observation. The sustained XRT flux in these VHE detections suggests an X-ray threshold for guidance to trigger VHE follow-up observations.

GRB	**Afterglow Detected**	**Follow-up Delay**	**Inferred XRT Flux after Delay [erg cm-2 s-1]**
130427A	Detected (Fermi-LAT)	∼20 Hrs (VERITAS)	4.1×10^{-11}
180720B	Detected (H.E.S.S)	∼10 Hrs (H.E.S.S)	7.7×10^{-11}
190114C	Detected (MAGIC)	∼6 Hrs (VERITAS)	6.5×10^{-11}
190829A	Detected (H.E.S.S)	∼4.5 Hrs (H.E.S.S)	9.9×10^{-11}

To solve this problem, the time dependence of the source count rate is assumed in a parameterized form $s(t)$ and the test statistic is re-derived following the strategy outlined by Li & Ma (1983).[19] The maximum likelihood estimate is used to optimize the signal and background count rates, collected within the *On* and *Off* observation regions defined as $\langle N_{on} \rangle = (\bar{b} + \bar{s}(t))T_{on}$ and $\langle N_{off} \rangle = \bar{b}T_{off}$ for observation times T_{on} and T_{off}, respectively. Assuming a Poisson distribution of counts, the general form of the test statistic is a ratio of the likelihoods for the null and alternate hypotheses $\mathcal{L}_0$ and $\mathcal{L}$:

$$\frac{\mathcal{L}_0}{\mathcal{L}} = \frac{\bar{b}_0^{N_{on}+N_{off}}}{\left(\bar{b}+\bar{s}\right)^{N_{on}} \bar{b}^{N_{off}}}, \tag{1}$$

where $\bar{b}$ and $\bar{s}$ are the time average background and signal count rates, and $\bar{b}_0$ is the time averaged rate when all counts observed are background.

To apply the time dependence, the T_{on} observation time is split into N bins of Δt, where the probability of the number of counts for each bin is independent and $N\Delta t = T_{on}$. For a parameterized $s(t)$, at the limit of $N \to \infty$, $\Delta t \to 0$, the likelihood ratio reduces to:

$$\frac{\mathcal{L}_0}{\mathcal{L}} = \frac{b_0^{N_{on}+N_{off}}}{\left(\Pi_{t_i \in \{t_{on}\}}(b + s(t_i))\right) b^{N_{off}}} \tag{2}$$

where $s(t) \equiv \theta \times t^{-1}$. The time dependence of the signal was assumed to be 1/t since it is most similar to many GRBs light curves,[20] where θ is a normalization constant for the time-dependent count rate.

This modified likelihood ratio was validated with a Monte Carlo simulation. Using a toy-model MC of a GRB, with 5×10^5 observations starting 2 min after burst trigger, the time-dependent signal $s(t) = \theta \times t^{-1}$, and the typical IACT background rate (1 γ /min), the following simulation results provided evidence for some additional conclusions (see also Figure 2 of[19]). For a 35-min observation, the mean significance over all the simulated observations increased from 4σ to 5σ once time

dependence is included, a 25% increase in sensitivity. For a 100-min observation: the simulated observations reveal that the overall significance improves from 3.4σ to 5.2σ with time weighting for that observation time. Comparing 35-min and 100-min simulations, the time-independent method has a reduced sensitivity from 4σ to 3.4σ as expected with the increase in background counts, while the time-dependent model increases from 5σ to 5.2σ, indicating that the time dependence allows for an improved estimate of the background and signal rates for longer observation times.

The simulation showed that the significance is dependent on the length of the observation. The standard significance[10] peaks and then declines over time as the background rate accumulates counts toward the *On* region and dilutes the signal counts. However, the time-dependent likelihood ratio grows monotonically if events are weighted to account for the GRB's time dependence, up to as much as 10-25% increase from the time-independent significance (see Fig. 3 of.[19]) Some common analysis software packages within the gamma-ray astrophysics field (e.g. CTOOLs) include a temporal model in the maximum likelihood fitting in addition to the spatial and spectral models.[21]

5. Gravitational Wave Follow-Up

Compact binary coalescences (CBCs) may trigger short GRBs (sGRBs). The detection of the binary neutron star (BNS) merger GW170817 was associated with GRB 170817A, a sGRB observed by *Fermi*-GBM triggered by a kilonova.[22,23] The multi-messenger detection of this event encourages a VHE follow-up program for future GW BNS trigger candidates. Both real-time VHE follow-ups (5.1) and archival searches by VERITAS are discussed (5.2).

5.1. *Real Time VHE Follow-Up*

The LIGO BNS sensitivity indicates a horizon between 111 Mpc and 134 Mpc from the third observation run (O3) for LIGO Livingston Observatory (LLO) and LIGO Hanford Observatory (LHO), respectively.[24,25] At this distance range, VHE photons are relatively unaffected by the extragalactic background light, which could generate a favorable selection of candidate GRB triggers for VERITAS follow-up. The joint detection of both GWs and VHE emission from GRBs may be possible through the real time follow-up of GW triggers by VERITAS.

The VERITAS follow-up strategy during O3 involved calculating the visibility of the GW localization region to select an observable portion. The visibility is the amount of time available for each sky coordinate for the next 24 hours. If the moon is above the horizon, the angular distance is limited to the range between 60° and 120° while the moon illumination is low enough. Using a Greedy Traveling Salesman heuristic, the pointings that tile the observable portion are defined and sorted such that the probability covered is maximized and the slewing time is minimized. The exposure per pointing is currently set at 5 min, for a maximum of three hours total.

Pointings were limited to those visible at $> 50^\circ$ elevation from VERITAS during the night.

The validation and summary of the VERITAS GW follow-up strategy was presented in.[26] The VERITAS follow-up of GW170104 and later observations were validated with a dedicated observation of the Crab Nebula under the same conditions described above, with six 5-min pointings tiled around the Crab Nebula position (Figure 2 in[26]). Table 1 in[26] lists a selection of O3 triggers followed up by VERITAS, including the BNS event GW190425.[27]

5.2. *Archival Search*

In addition to real-time GW follow-ups, VERITAS also developed an archival search for VHE gamma-ray emission in coincident observations of sub-threshold LIGO/VIRGO GW candidates.[28] In this search, there were 7 sub-threshold candidates found in serendipitous coincidence with VERITAS archival observations (11 pointings, $\leq$ 10 hr). The candidates were selected from a published collection of sub-threshold triggers from O1.[29]

An important consideration for other observatories while evaluating this algorithm is that there was no extra cost to the IACT or a dedicated observation campaign. Although VERITAS has a small field of view (FoV) (3.5° diameter), this is large enough for coincident observations. However, the sensitivity decreases for greater distance away from the camera center. Cross-checking the list of published sub-threshold triggers for coincident VERITAS observations was completed offline. In the search, observations were considered coincident if they passed good weather selection criteria, were contained within the 90% probability region of the original LIGO/Virgo candidate map, and overlapped with the time window $-10 \leq t_0 \leq 10^4$ seconds of the coalescence time t_0.

The archival search of VERITAS observations yielded upper limits across the field of view for each observation run. For each observation, the flux upper limit was calculated at each pixel of that observation and the geometric mean was reported to characterize the observed field for comparison with the LIGO sub-threshold candidate probability region. Each of the candidate observation upper limits was then compared to a fluence model based on sGRB 090510, for a 75 Mpc distance over the [0.24 TeV, 30 TeV] energy band. This distance was chosen to match the LIGO sensitivity range for O1, while the energy range was chosen to match the VERITAS energy range.

The comparison of the GRB model to the VERITAS observations shows an estimated sensitivity to $\approx 10^{-3}$ times the fluence of the GRB. The probability that at least one truly astrophysical merger was observed by VERITAS within the observation was estimated to be 0.04%. These results indicate that archival searches of coincident VHE observations with GW candidates may constrain the fluence of the progenitor burst and provide meaningful upper limits to the broadband spectral and light curve models that characterize these events. The weak constraints

shown here indicate that stronger conclusions may be possible provided that there are enough coincident observations with sub-threshold GW candidates or more opportune events.

6. Summary and Outlook

In summary, VERITAS has an active and exciting GRB follow-up program. Since 2006, over 200 bursts have been followed-up. While no detections were made in the VHE range, meaningful upper limits were derived for a small selection of bursts. Both GRB 130427A and 150323A yielded constraints on the environment of the bursts and VHE production mechanism.

Optimizations were made to improve the likelihood of new detections. The addition of a *Swift*-XRT-guided observation strategy to optimize for bright bursts increased the amount of time dedicated to X-ray bright candidate bursts, increasing the likelihood of VHE detection. A time-dependent significance calculation improved the sensitivity to weak bursts, weighing the most likely time bins more heavily in the calculation.

The gravitational wave prompt follow-up program provides another source of triggers for sGRBs, increasing the number of GRB targets and the likelihood of detection. The GW sub-threshold archival search is a promising new method for seeking signals in archival data and setting constraints on the fluence of potential sGRB counterparts.

MAGIC view of Gamma-Ray Bursts at very high energies

A. Berti* on behalf of the MAGIC collaboration
Max-Planck-Institut für Physik,
Munich, 80805, Germany
**E-mail: aberti@mpp.mpg.de*

The detection of gamma-ray bursts (GRBs) is one of the main scientific targets pursued by the MAGIC collaboration since almost 20 years. The MAGIC telescopes were specifically designed for this purpose: the main figures of merit are the fast slewing speed (7deg/s), the low energy threshold (50 GeV at zenith) and the high sensitivity in the low energy regime. These features make MAGIC one of the most suitable instrument for the follow-up and detection of GRBs. After more than 15 years of dedicated searches, finally the first detection at teraelectronvolt energies of a GRB, namely GRB 190114C, was achieved by the MAGIC collaboration, revealing a new emission component in the afterglow phase. This discovery opened up a new era in field of GRB studies, which is now witnessing other detections, as demonstrated with the case of GRB 201216C. Furthermore, a hint of detection by MAGIC from the short and nearby GRB 160821B gives precious hints on the possible very high energy emission from this class of bursts, also in relation to searches of gravitation wave counterparts. Therefore, MAGIC is giving a crucial contribution to GRB physics, leading to a better understanding of the mechanisms underlying these peculiar objects. In this contribution I will introduce the MAGIC follow-up program, focusing on the aspects which led to the successful detection of GRBs and highlighting some key results. Finally, I will present the future challenges in these observations, discussing how MAGIC can contribute even more to the field.

Keywords: Gamma-ray bursts; MAGIC; very-high-energy

1. Introduction

The search for very high energy (VHE, $E \gtrsim 100\,\mathrm{GeV}$) emission from gamma-ray bursts (GRBs) is one of the key projects of the imaging atmospheric Cherenkov telescopes (IACTs) currently in operation:

- MAGIC (*Major Atmospheric Gamma-ray Imaging Cherenkov*), located in the Canary island of La Palma, Spain;
- H.E.S.S. (*High Energy Stereoscopic System*), operative in Namibia;
- VERITAS (*Very Energetic Radiation Imaging Telescope Array System*), located in Arizona.

In these proceedings we focus on MAGIC, a system of two Cherenkov telescopes located at about 2200 meters above sea level in the Observatorio del Roque de Los Muchachos (ORM) in La Palma, Canary Islands, Spain. MAGIC started operations in late 2003 as a single telescope (MAGIC-I) and in 2009 a second one (MAGIC-II) was added to perform stereoscopic observations. In 2012 the camera of MAGIC-I was upgraded in order to be a copy of the one installed in MAGIC-II. Both telescopes have a reflector of 17 meter diameter, corresponding to a reflective surface

of $\sim 236\,\mathrm{m}^2$. This allows MAGIC to reach an energy threshold as low as 50 GeV at trigger level when pointing close to zenith. This is an important figure of merit for the observation of GRBs, since they are sources typically located at high redshift and the VHE gamma rays are heavily absorbed due to the interaction with the low energy photons of the extragalactic background light (EBL). Other features making MAGIC a suitable IACT to perform GRB observations are the following (see e.g. ref. 1):

- the high sensitivity even at the lowest energies. MAGIC has a sensitivity of 0.7% of the Crab Nebula flux above 220 GeV in 50 h of observation;
- the large effective area, of the order of $10^5\,\mathrm{m}^2$ which allows to collect many gamma rays to perform detailed temporal and spectral studies;
- the high duty cycle, which is the result of the possibility to observe even during moon time or when pointing to high zenith angles;
- the relatively low weight thanks to the carbon fiber structure, ~ 70 t per telescope, allowing fast rotation at $\sim 7^\circ\,\mathrm{s}^{-1}$ in the so-called "fast mode";
- the automatized reaction to GRB (and other transients) alerts, reducing the possible delay introduced by a human in the loop.

Indeed, MAGIC was designed with the detection of GRBs in the VHE range as one of its primary scientific goals, therefore many hardware and software developments aimed at improving the performance of the telescopes at the lowest energies. An important step in this direction was the development of the novel Sum-Trigger system, which was used in the past to detect pulsed emission from the Crab pulsar[2] down to 25 GeV and more recently adopted to detect the Geminga pulsar in the 15-75 GeV energy range.[3]

In these proceedings we will describe the GRB follow-up program within MAGIC and the results that could be achieved in the recent years. Finally we will discuss future prospects of GRB observations with MAGIC, highlighting the scientific and technical challenges lying ahead.

2. The MAGIC GRB follow-up program

Even before the beginning of current generation IACTs operation and the launch of the *Fermi* satellite, many theoretical studies predicted that GRBs should have been emitters of high energy and very high energy gamma rays. Such studies considered different mechanisms involving both leptonic and hadronic processes. While high energy emission was detected both in the prompt and afterglow phases of GRBs with *Fermi*-LAT, IACTs could not achieve significant detection in the VHE range for many years despite a considerable amount of hours devoted to GRB observations. The search for VHE emission from GRBs is crucial to answer some important questions, such as the following (not an exhaustive list):

- do GRBs emit at VHE?
- is VHE emission relevant e.g. from the energetic point of view?

- what is the emission process (or processes)? is it a continuation of the low energy spectrum or is it a new emission process?
- can the process producing VHE gamma rays contribute also at lower energies?
- is there VHE emission both in the prompt and the afterglow phases?
- is VHE emission present in both short and long GRBs?

In order to achieve the detection of GRBs, a specific program focuses on their follow-up, including both technical and strategy aspects.

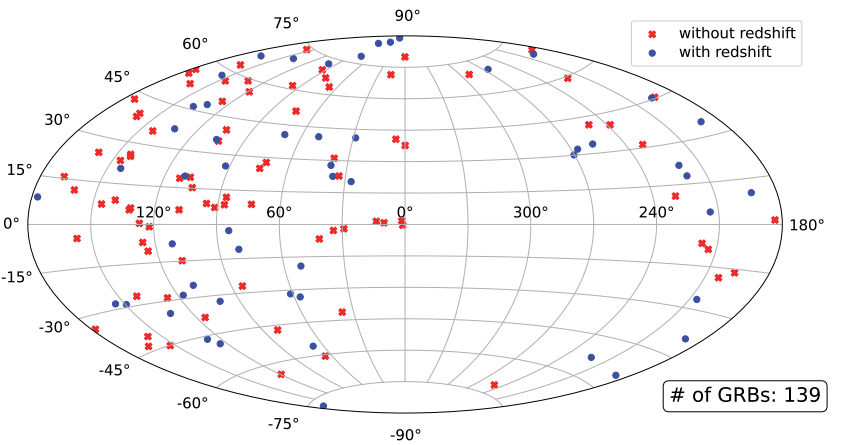

Fig. 1. Aitoff projection skymap showing the sky locations of the GRBs observed by MAGIC up to June 2021. GRBs with redshift estimation are denoted with blue filled circles, while those without redshift with red crosses.

From the technical point of view, given the small field of view of the telescopes (3.5°) and the serendipity of GRBs in both time and sky region, MAGIC relies on external alerts from other instruments. In particular, an automatic alert system (AAS) is in place since 2003 and it is used to receive GRB and other transients (high energy astrophysical neutrinos, gravitational waves, flaring *Fermi* sources, soft gamma-ray repeaters etc.) alerts, mainly from the GCN (*gamma-ray coordinates network*). After receiving a GRB alert, the AAS validates it and checks for the visibility from the MAGIC site according to some predefined criteria. If the GRB sky coordinates are immediately observable, the ongoing observation is stopped and an automatic procedure prepares the telescopes for the GRB observation. In more detail, the telescopes slew towards the GRB position in the so-called "fast mode". During the movement, other subsystems are prepared for data taking e.g. the DAQ is restarted, proper discriminator thresholds are loaded depending on the GRB position with respect to the galactic plane and to the night sky background

and mirrors are focused according to the local zenith/azimuth of the GRB. This automatic procedure was upgraded in 2013 to make it more reliable and reduce failures to a minimum. In particular, in the upgraded automatic procedure the DAQ system is not stopped but just reconfigured, and the observation is started in wobble mode, the standard pointing for MAGIC data taking.

During the years, the AAS was updated by adding new alert types and by changing the implemented follow-up strategy. For example, the AAS allows to observe GRBs even at late time with respect to the trigger time, given that *Fermi*-LAT could detect high energy emission several hours in the afterglow phase of some GRBs. A major update in the AAS was deployed in early 2021, namely the standardization to the VOEvent format.[4] Currently the AAS receives alerts from the GCN broker, but other brokers can be easily added depending on the science cases (e.g. supernovae, tidal disruption events etc.). All in all, the AAS is becoming more and more a multimessenger system, with features being added related to different follow-up strategies.

Within the GRB follow-up program, MAGIC observed 139 GRBs from 2004 up to June 2021. A skymap showing the sky positions of the observed GRBs is shown in Figure 1. Of the 139 GRBs, 53 of them have a reported redshift, of which 13 have a redshift less than 1. Most of the GRBs observed by MAGIC are long GRBs and triggered by Swift-BAT, with a minority of alerts followed-up after alerts from Fermi-GBM, Fermi-LAT and INTEGRAL (or HETE in the first years of MAGIC operation).

As far as the delay of the observation is concerned, Figure 2 shows the time delay (computed as the difference between the beginning of the observation and the trigger time of the burst) against the zenith angle at the beginning of the observation. 37 GRBs have a delay less than 100 s, 25 were followed-up within one minute from the onset. 12 GRBs were observed with a delay less than T_{90}, so that the prompt or early afterglow phases could be observed. The fastest follow-up to date was performed in the case of GRB 160821B, where the telescopes started data taking 24 s after the burst onset. Interestingly, all the GRBs detected by MAGIC or with a hint of signal were observed with a delay smaller than 100 s.

3. MAGIC results on GRB observations

3.1. *Status at MG15 meeting*

In 2018 a similar topic was presented at the 15th edition of the Marcel Grossmann meeting. At the time, MAGIC and other IACTs did not detect any GRB in the VHE range, even if a large effort was put to organize efficient GRB follow-up programs. Some interesting observations were reported by the three collaborations, namely GRB 060602B occurring in the field of view for H.E.S.S., GRB 130427A (also known as the "monster burst") by VERITAS and the short GRB 160821B by MAGIC. However no significant detection could be achieved.

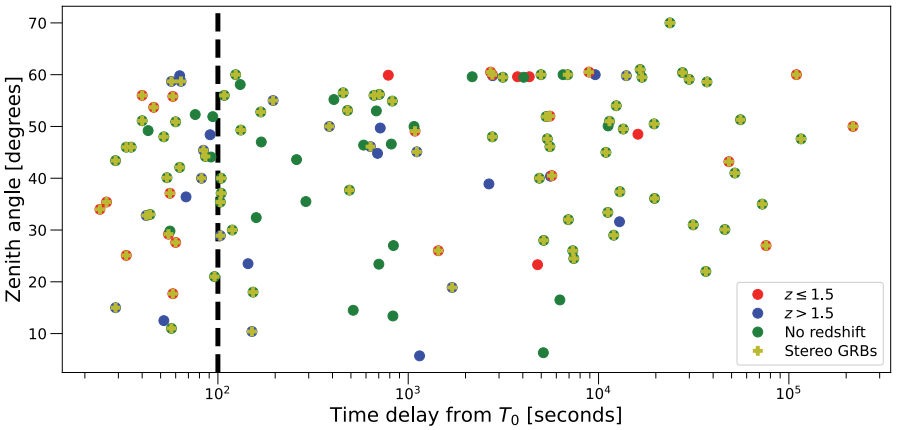

Fig. 2. Plot showing the delay of the start of the observation for GRBs observed by MAGIC up to June 2021. On the vertical axis, the zenith angle at the beginning of the observation is shown. Points with crosses denote GRBs observed in stereoscopic mode, those without were observed in mono mode.

The situation dramatically changed in 2019, which can be considered a golden year for GRB studies. Indeed, in January 2019 the MAGIC collaboration reported the historical detection of the long bright GRB 190114C in the VHE range, followed by the announcement by H.E.S.S. in May 2019 at the Cherenkov Telescope Array (CTA) Symposium in Bologna about the detection of GRB 180720B. Later in the year, at the end of August, the H.E.S.S. collaboration reported the detection of the long and very close GRB 190829A. In 2020 MAGIC reported a strong hint of signal from GRB 201015A and a detection from GRB 201216C. Therefore, the last years saw the long awaited birth of the VHE era for GRBs, finally allowing to explore the physics of these objects at such energies.

In the following section we describe the latest results by MAGIC on the search for VHE emission by MAGIC, focusing on the breakthrough detection of GRB 190114C and on the other detection of 2020.

3.2. *Recent MAGIC GRB results at MG16*

3.2.1. *GRB 190114C*

As mentioned in section 3.1, 2019 was the year starting a new era in GRB studies, which can be called the VHE era. On January 14th 2019 MAGIC detected a very significant (at the 50σ level) emission between 300 GeV and 1 TeV from the long and bright GRB 190114C,[5] initially detected by *Swift*-BAT and *Fermi*-GBM. The results on this GRB were presented in two papers, Refs. 6 and 7, one describing the MAGIC observation and detection, the second focusing on the multi-wavelength picture and on the physical interpretation of the VHE emission. In these proceedings

we will focus on the main findings from GRB 190114C observations, for more details the reader can refer to the aforementioned publications or to the contribution by D. Miceli from these proceedings series.

GRB 190114C was a bright ($E_{\rm iso} \sim 3\times10^{53}$ erg in the 1 to 10^4 keV energy range), long ($T_{90} = 362$ s as measured by *Swift*-BAT) and quite nearby ($z = 0.4245$) GRB. As shown in Figure 3, MAGIC received the alert from *Swift*-BAT 22 seconds after the onset of the GRB and started observations about 1 minute after the GRB trigger under moderate moon conditions at a relatively high zenith of 58°. From the real-time analysis the GRB was detected with a significance of 20σ in the first 20 minutes of observations above an approximate threshold of 300 GeV, later confirmed as 50σ in offline analyses, see Figure 4. The detection was reported as quickly as possible to the astrophysical community to strongly encourage the follow-up of this event at other wavelengths.

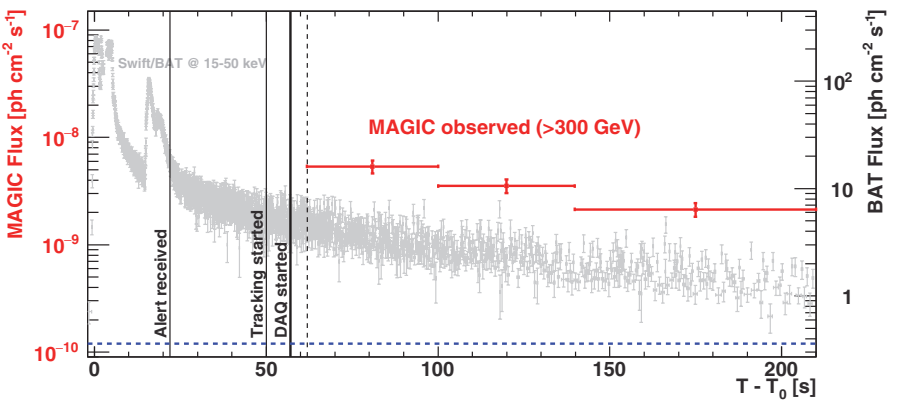

Fig. 3. Light curves for MAGIC and Swift-BAT. Vertical solid lines show the times of events related to the MAGIC automatic procedure. Extracted from Ref. 6.

One of the first questions to be answered was if the emission detected by MAGIC was related to the prompt or afterglow phase of the GRB. While the value of T_{90} may indicate that such emission could belong to the prompt, detailed spectral and temporal studies of the keV-MeV data show that at $\sim T_0 + 25$ s the properties of such low energy emission is typical of the afterglow phase. This is additionally confirmed by the similar temporal decay index between the X-ray (from *Swift*-XRT between 0.1 and 1 keV) and the VHE (between 300 GeV and 1 TeV) energy light curves.

The intrinsic spectrum of the GRB is compatible with a power law with spectral index of $\alpha_{\rm int} = -2$ between 0.2 and 1 TeV, with no indication of any break or cutoff beyond those energies at the 95% confidence level. Such flat spectrum indicated that the energy output in the VHE range is relevant, indeed turning out to be

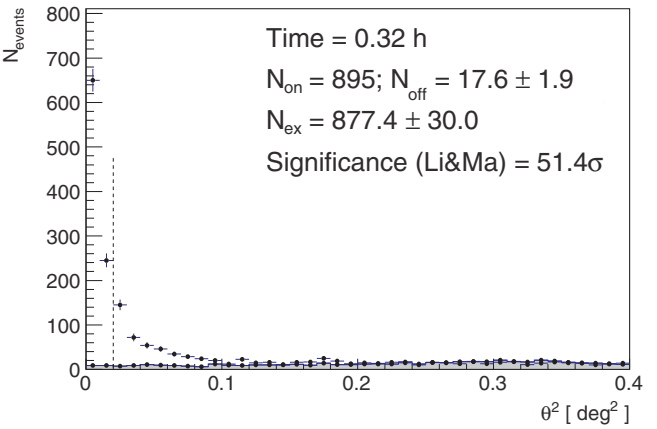

Fig. 4. Plot showing the significance of the gamma-ray signal detected by MAGIC from GRB 190114C. Extracted from Ref. 6.

comparable to the one at low energies. Given the high absorption of the VHE flux by the EBL at the redshift of the GRB, the spectrum observed by MAGIC is rather steep and best described by a power law with index $\alpha_{\rm obs} = -5.43 \pm 0.22$. This was tested against different EBL models, resulting in similar spectral indexes compatible within the statistical uncertainties.

The most important question was related to the origin of the emission detected by MAGIC. The similarity of the temporal decay in X-ray and VHE energy light curves suggests that the emission processes should be linked. While the simplest hypothesis is that the processes producing the X-ray and VHE photons are the same, namely synchrotron emission from relativistic electrons accelerated at the external shock in the afterglow of the GRB, this explanation is ruled out if one takes into account that synchrotron photons reach a maximum energy. This is the so-called burnoff limit and in the external shock of GRBs can be described by the equation $E_{\rm syn,max}(t) \approx 100(\Gamma_b(t)/1000)$GeV ($\Gamma_b(t)$ is the Lorentz factor of the GRB blastwave as a function of time). Even assuming a Lorentz factor of ~ 1000, which is not typical for GRBs and in any case it decreases with time, the maximum energy of the photons produced by synchrotron is at most around 100 GeV, even considering different density profiles of the interstellar medium density. This value is much lower than the lowest energy of the photons detected by MAGIC, therefore it is reasonable to assume that the VHE emission is due to another process. In addition, prolonging the low energy synchrotron spectrum (from GBM, XRT and LAT data) would underestimate the MAGIC flux by one order of magnitude, strengthening the conclusion that the VHE photons are indeed produced by a different mechanism. However we note that the burnoff limit interpretation assumes one emission region, while having more emission regions may allow synchrotron photons to reach higher energies.

In the assumption that the VHE emission is not due to synchrotron, the most simple alternative is the so called synchrotron-self Compton (SSC), where the synchrotron photons are upscattered by their parents electrons, thus increasing their energy. The SSC process is not new in VHE astrophysics, indeed it is commonly detected in sources like active galactic nuclei, where the spectral energy distribution shows two peaks, one at low energies due to synchrotron emission and a second one at higher energies, often at in the VHE energy range, due to the SSC process. In GRB 190114C the modeling of the GRB 190114C multi-wavelength data with a synchrotron plus SSC emission model within the external shock scenario in the afterglow shows exactly this two peaks features, therefore confirming the presence of a new emission component never observed before. Another remarkable result is the fact that the parameters describing the broadband emission of GRB 190114C have values similar to the ones found in previous studies of GRB afterglows when data only up to GeV energies were considered. This may hint to the possibility that VHE emission from SSC may be present in all GRBs and that it could be detected by IACTs if favorable conditions apply i.e. a low enough redshift and good observing conditions. This hypothesis can be confirmed only with more GRBs detected in the VHE range, as the current number of GRBs is not enough to draw firm conclusions.

3.2.2. *GRB 201015A and GRB 201216C*

The detection of GRB 190114C gave additional momentum to the searches of GRBs with MAGIC. This led to other two important observations in 2020.

The first observation concerns GRB 201015A, a burst detected by *Swift*. While the GRB showed some features resembling short GRBs, the detection of a supernova signature five days after the onset make this a long GRB.[8] Despite being at a redshift very similar to the one of GRB 190114C ($z = 0.426$), GRB 201015A has a relatively low luminosity of $E_{\rm iso} \sim 10^{50}\,{\rm erg}$, i.e. three order of magnitude lower. MAGIC started the observations after $\sim 1\,{\rm min}$ after the onset of the GRBs and it reported a hint of detection at the level of more than in 3σ from offline analyses.[9] This strong hint is very interesting if compared to the detection of the low luminosity GRB 190829A by the H.E.S.S. collaboration, located at a much lower redshift $z = 0.08$. For more details, the readers may refer to Suda et al. 2021.

In a second observation in December 2020, MAGIC detected another burst, GRB 201216C.[10] Again, this was a long GRB ($T_{90} = 48\,{\rm s}$) with similar energetics to GRB 190114C ($E_{\rm iso} \sim 5 \times 10^{53}\,{\rm erg}$), but much more distant, having a redshift of $z = 1.1$. A clear detection was achieved, and first preliminary results were presented in ICRC 2021. The most remarkable feature for this GRB is the very high redshift, enlarging the spectrum of GRB properties characterized in VHE observations.

3.2.3. *GRB 160821B*

While all GRBs currently detected at VHE belong to the long class, some progress was done also for short GRBs. Being intrinsically less energetic than long GRBs but

at relatively lower redshifts, their detection may be feasible with current IACTs. A good indication for such hypothesis is the observation of GRB 160821B by MAGIC, a short GRB detected by *Swift* located at $z = 0.16$. Additionally, short GRBs are linked with binary neutron star systems, which were proven to be gravitational waves emitters with the GW170817 event. GRB 160821B is one of the few short GRBs with a confirmed kilonova emission, pointing to a possible binary neutron star system as progenitor. As mentioned in section 2, MAGIC started data taking 24 s after the onset of GRB 160821B. The weather conditions were not favorable: moonlight was present and increasing during the observation, the zenith of the target was rather high (between 34° and 55°) and the first part of the data was affected by clouds, resulting in a reduced atmospheric transmission. Despite the unfavorable observing conditions, an evidence of a gamma-ray signal was found at a significance of $\sim 3\sigma$ above ~ 0.5 TeV.[11]

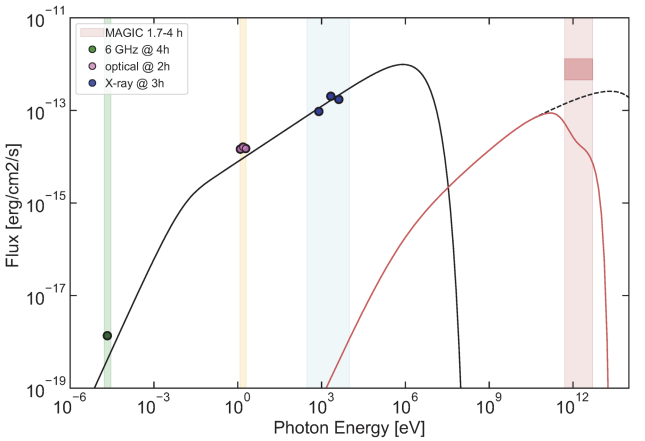

Fig. 5. Spectral energy distribution of GRB 160821B and modeling curves. The solid black line models the synchrotron radiation, while the dashed black line is the intrinsic SSC emission. The red line takes into account the absorption by the EBL. The red box only indicated the putative flux level from MAGIC. Extracted from Ref. 11.

If we assume that the gamma-ray excess is genuine emission from GRB 160821B, the flux predicted by the SSC process in the external forward shock scenario is in tension with the observed TeV flux, see Figure 5. Other scenarios were considered in order to explain the MAGIC data, from proton synchrotron emission, photohadronic cascade emission, external compton, multiple zone emission or SSC from the reverse shock. While hadronic processes are disfavored due to their inefficiency and large energy requirements, the other possibilities are not ruled out. This points to still poorly understood properties of short GRBs, which needs more observations at GeV-TeV energies in the future to fill in the picture, also in relation to gravitational wave searches.

4. Future perspectives for GRBs detection with MAGIC and conclusions

The recent detection of GRBs in the VHE regime opened a new era in this field. Such discoveries were long awaited and they are the result of a continued effort with improvements from the technical and strategy point of view. For the next years, there are other challenges that need to be faced in the search for VHE emission with MAGIC.

First of all, the number of detected GRBs is still low and they were bursts with quite different properties (e.g. distance, brightness). Therefore it is difficult to infer what could be the main factors within a GRB that favor the production of VHE gamma-rays. Despite this, a property seems to be shared among all the GRBs, namely the similar time decay between the X-ray and the VHE flux. In a recent study by Campana and collaborators instead, they discuss the possibility of a relation between a high X-ray column density and the presence of TeV emission, which seems to find confirmation considering the detected GRBs.

A second challenge for MAGIC is the detection of VHE emission in the prompt phase of a GRB. This would constitute another major breakthrough in the field, finally shedding light on which process is responsible for the initial flash of GRBs. MAGIC proved already to be able to begin GRB follow-ups very close to the onset, therefore observing during the late prompt-early afterglow phase of a dozen of GRBs. Therefore, we might expect to have a detection of VHE gamma-rays during the prompt phase to happen soon.

The third challenge was mentioned in section 3.2.3, that is the detection of short GRBs in the VHE regime. The hint of detection reported by MAGIC gives a strong indication that this goal can be achieved. In this case the number of events is quite reduced, given that the majority of GRB alerts received by MAGIC are long GRBs. However, the opportunities may increase with the beginning of the new observational run by LIGO, Virgo and Kagra expected to start in late 2022, O4. As exemplified by the GW170817/GRB170817A event, we may search for short GRBs in spatial and temporal coincidence with gravitational wave signals from the coalescence of binary neutron star or neutron star-black hole systems. As the localization of the GW events is expected to be improved, and thanks to more and more refined follow-up strategies involving both satellite-borne or ground-base telescopes, this might give MAGIC and other IACTs additional chances in detecting short GRBs.

To summarize, the recent detection of GRBs in the last years had clearly a major impact in GRB physics, and gave additional boost to searches in the VHE regime and beyond (e.g. with current and future extensive air shower arrays). The primary goal for MAGIC is to detect more GRBs, profiting of every opportunity and trying to clear the challenges mentioned above. One basic question is if SSC can model the TeV emission from GRBs in a generic way, or if other processes may instead explain it. A possible way to test such hypothesis would be to have simultaneous observation by MAGIC and Fermi-LAT partially overlapping in energy. Assuming

the two experiments give similar results in the overlapping energy region (at a few tens of GeV), a break in the MAGIC spectrum at few tens of GeV after which it rises would give a clear indication of an inverse Compton component. Such possibility is realistic given the recent result by MAGIC on the Geminga pulsar, where the SumTrigger system was used to achieve an energy threshold as low as 15 GeV so that part of the spectrum observed by MAGIC overlaps with the one by Fermi-LAT.

From the discussion in these proceedings, it is clear that the field is still young and the possibility of important discoveries is high. MAGIC proved to be up to the expectations and surely it will play a major role in the coming years as well, contributing even more to unveiling many mysteries related to GRBs.

It has been established that Gamma-Ray Bursts (GRB) can produce Very High Energy radiation (VHE, $E > 100\,\mathrm{GeV}$), opening a new window for investigating particle acceleration and radiation properties in the most energetic domain. We expect that next-generation instruments in this energy regime, such as the Cherenkov Telescope Array (CTA), will mark a huge improvement in their observation. However, constraints on the target visibility and the limited duty cycle of Imaging Atmospheric Cherenkov Telescopes (IACT), affect their ability to react promptly to transient events. Here we use a grid of instrument performance estimates, based on the Extensive Air Shower (EAS) array concept proposed by the Southern Wide Field-of-view Gamma-ray Observatory (SWGO) collaboration, to evaluate SWGO's potential to detect and track VHE emission from GRBs. Observations by the *Fermi* Large Area Telescope (*Fermi*–LAT) at high energy ($E > 10\,\mathrm{GeV}$), identified some events with a distinct spectral component, which can represent a substantial fraction of the emitted energy and possibly occur very early in the process. Using models based on these properties, we estimate the possibilities that a wide field of view and large effective area ground-based monitoring facility has to probe VHE emission from GRBs. We show that the ability to monitor VHE transients with a nearly continuous scanning of the sky grants us the opportunity to simultaneously observe electromagnetic counterparts to gravitational waves and relativistic particles sources up to cosmological scales, in a way that is not accessible to IACTs.

Keywords: Instrumentation: detectors; gamma rays: general; gamma ray burst: general.

1. Introduction

The study of Gamma-Ray Bursts (GRB) represents one of the most challenging and fascinating frontiers of High Energy Astrophysics. Although they were discovered in the first years of space explorations with high energy detectors,[1] several aspects of their origin, their power, and their radiation mechanisms are still unclear. We know that GRBs are originated by ultra-relativistic jets of plasma, which are produced during the extremely fast accretion process that follows the collapse of a very massive star ($M \geq 20\,\mathrm{M}_{\odot}$) or the merger of a binary neutron star (NS), to form a *magnetar* or a black hole.[2] The process produces a flash of energetic photons, named *prompt emission*, followed by a smoothly decaying signal, called *afterglow*. Looking at the duration of the prompt phase, GRBs appear to show a bimodal distribution, where we distinguish a class of short events, with a prompt stage lasting less than 2 s, and another of long ones, whose prompt emission takes place for much longer times.[3,4] The two classes of events are consistent with two distinguished possible source types. Long GRBs have been associated with supernova explosions,[5,6] while the short ones fit better in the compact binary merger scenario,[7] as eventually demonstrated by the GRB 170817A–GW 170817 multi-messenger association that was also detected as a *kilonova*.[8–10]

In the past few years, observations performed with ground based Imaging Atmospheric Cherenkov Telescopes (IACT), such as MAGIC[11] and H.E.S.S.,[12] found evidence for Very High Energy γ-ray emission (VHE, $E \geq 100\,\mathrm{GeV}$) in the afterglow of some GRBs.[13,14] In addition, analysis of the data collected by the *Fermi* Large Area Telescope (*Fermi*-LAT)[15] demonstrated the existence of a high energy component in the spectra of some bright GRBs that extends above the 10 GeV energy range and can be detected also in association with the prompt emission.[16–18] Understanding the origin and the distribution of VHE radiation from GRBs is a key issue for their correct interpretation. It is expected that next generation γ-ray instruments, such as, for instance, the Cherenkov Telescope Array (CTA),[19] will provide exceptional new data in this field. Unfortunately, the unpredictable nature of GRBs and their fast spectral evolution makes it extremely difficult, for instruments with narrow field of view (FoV), of the order of few square degrees, to re-point and track GRB emission within very short times (below 10 s). A possible solution to this problem is using Extensive Air Shower detector arrays (EAS) to monitor large areas of the sky, with an instantaneous FoV of more than 1 sr and a nearly continuous duty cycle. Here we discuss the observational opportunities that a new instrument, based on a next-generation EAS array concept investigated by the Southern Wide-field-of-view Gamma-ray Observatory (SWGO),[20] will open in the study of GRBs.

This contribution is structured as follows: in §2 we describe the known and the expected VHE properties of GRBs; in §3 we present the potential monitoring

capabilities of SWGO; finally, in §4 we discuss our results and we draw our conclusions.

2. VHE emission from GRBs

Several arguments suggest that GRBs should be able to produce prompt VHE radiation. The most likely interpretation of GRBs invokes relativistic shocks occurring either within the magnetized jet plasma (*internal shocks*, generally associated with the prompt stage), or between the jet and the surrounding environment (*external shocks*, more often considered as the source of the afterglow emission). In both cases, the energies associated with particles and magnetic fields are high enough to produce efficient leptonic radiation mechanisms and possibly to activate hadronic processes.[21–23] The combination of temporal and spectral properties of the emitted radiation provides fundamental indications on the characteristics of the source.

In general, a large fraction of the energy that a GRB releases in the prompt phase is found in the spectral range falling between few hundreds keV to some MeV.[24] The spectrum comes in the form of a combination of power-law components, known as the *Band function*.[25] The presence of relativistic charged particles in an intense magnetic field leads to the natural expectation that powerful synchrotron and inverse Compton radiation should be emitted.[26] While the prompt emission is characterized by fast pulse-like variability, with time-scales down to few milliseconds,[27] implying extremely compact emission regions, the observation of photons up to the MeV and even the GeV energy range requires very large bulk Lorentz factors ($\Gamma >> 100$), in order to suppress pair production opacity. In these conditions, the inverse Compton scattering of synchrotron radiation may lead to the production of photons up to the TeV domain.[28] The occurrence of ultra-relativistic shocks in high density environments, on the other hand, is theoretically able to activate photo-pion interactions that can extend the spectra beyond 300 GeV[23] and lead to potential associations with neutrino events.[29]

So far, the direct detection of VHE radiation has only been possible in the afterglow of a limited number of GRBs, thanks to ground-based follow up observations.[13,30–32] However, the monitoring campaign carried out by the *Fermi*-LAT space observatory led to the identification of a high energy spectral component, coming in the form of power-law emission, that appears to be a common feature of bright GRBs and may even arise very early in the event.[33] Due to the limited collecting area and the typical short duration of GRBs, the LAT observations are not able to place strong constraints on the VHE component of GRBs, as it is suggested by the fact that *Fermi* did not detect photons above ~ 30 GeV from GRB 190114C, while the same event was firmly detected up to almost 1 TeV. As a consequence, the results of *Fermi*-LAT observations can be used as a starting point to estimate the possible extension of the GRB properties to the VHE domain and thereby evaluate their detection opportunities for other instruments.

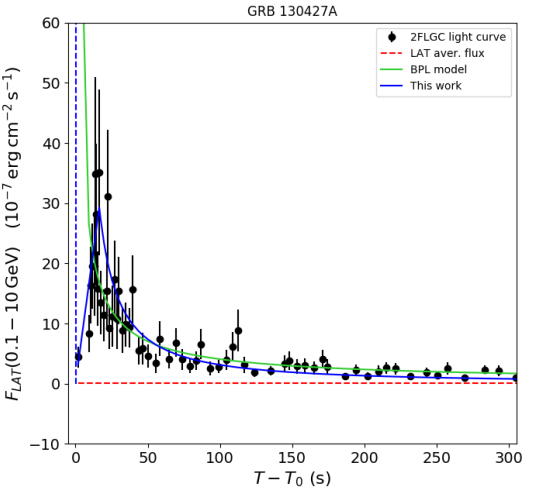

Fig. 1. Comparison between the *Fermi*-LAT light curve of GRB 130427A and the model based on Eq. (1) and Eq. (2). The vertical blue dashed line marks the start of the LAT signal temporal window, the red horizontal line is the average energy flux collected during the entire time of emission, the green continuous line is the 2FLGC power-law fit to the data, while the blue continuous line is a model using the light curve of Eq. (2).

Usually, we can express the high energy spectrum of a GRB as a function of energy in the form of:[a]

$$\frac{\mathrm{d}N(t)}{\mathrm{d}E} = N_0(t)\left(\frac{E}{E_0}\right)^{-\alpha}\exp[-\tau(E,z)] \quad [\mathrm{ph\,cm^{-2}\,s^{-1}\,GeV^{-1}}], \tag{1}$$

where $N_0(t)$ is the flux of photons per unit energy observed at time t, E_0 is the pivot energy, α is the spectral index, which is often within the range $1.5 \leq \alpha \leq 3$, with an average value close to 2, and $\tau(E,z)$ is the opacity due to pair production on Extragalactic Background Light photons (EBL), given as a function of energy and redshift. The temporal evolution of the flux is typically well represented by a power-law, or a broken power-law, that can be written as:

$$N_0(t) = \begin{cases} N_{peak}\left(\dfrac{t-T_0}{T_{peak}-T_0}\right) & \text{for} \quad T_0 \leq t \leq T_{peak} \\ N_{peak}\left(\dfrac{t}{T_{peak}-T_0}\right)^{-\gamma} & \text{for} \quad t > T_{peak}, \end{cases} \tag{2}$$

where we denoted with T_0 the trigger time, with T_{peak} the time taken to achieve peak emission, with N_{peak} the maximum flux, and with γ the temporal evolution index, which is often found to be $1 \leq \gamma \leq 2$.

[a]We assume for simplicity that the temporal evolution of the spectrum is only limited to a scaling factor, without relevant spectral changes.

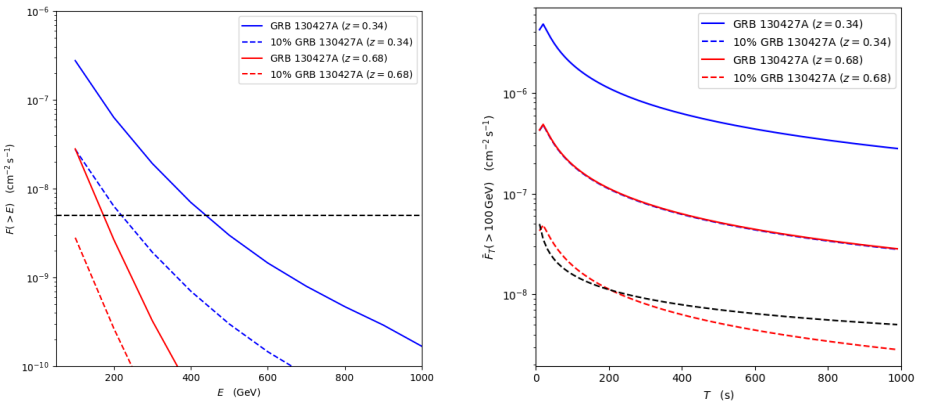

Fig. 2. **Left panel:** average photon flux expected above any given energy in 1000 s for a burst with the spectral and temporal characteristics of GRB 130427A (blue continuous line), an identical burst with 10% its strength (blue dashed line) and the same previous cases computed for twice the measured redshift (red continuous and dashed lines). The horizontal black dashed line represents a reference flux limit of $5 \cdot 10^{-9}$ ph cm^{-2} s^{-1}. **Right panel:** instantaneous integral photon fluxes, expected above 100 GeV as afunction of time, compared with the detection threshold, in the assumption that the limiting flux scales as the square root of the observation time.

Using the second catalog of *Fermi*-LAT detected GRBs (2FLGC),[33] which provides measurements of the observed photon fluxes, in the energy range between 0.1 GeV and 10 GeV, together with information on the spectral index and on the light curve shape, for a sample of GRBs observed during 10 years of regular monitoring operations, we are able to apply Eq. (1), with the inclusion of Eq. (2), to estimate the expected high energy fluxes as a function of time, as it is illustrated for instance in Fig. 1. In principle, we can extend this type of spectra to the VHE domain and, thus, obtain an estimate of the expected fluxes. In practice, this operation is not directly possible, due to the lack of a redshift measurement for the majority of the LAT detected GRBs, which implies an unknown EBL opacity in Eq. (1). Although the effects EBL are generally negligible for the observed LAT band, they become quickly very important at higher energies, with a typical γ-ray horizon set by $\tau = 1$, which, for $z \approx 1$, already occurs at $E = 100$ GeV.[34] For this reason, we combined the spectral and temporal fits, which we obtained from the LAT data, with a set of simulations, aiming at estimating the effects of EBL opacity on the VHE extension of the GRBs that resulted in the brightest LAT observed fluxes.[35]

3. GRB monitoring with SWGO

A direct consequence of Eq. (1) is that the observation of VHE radiation, particularly from fast transient sources, requires the use of large instrumented areas. This characteristic can only be offered by ground-based facilities, such as IACTs or EAS

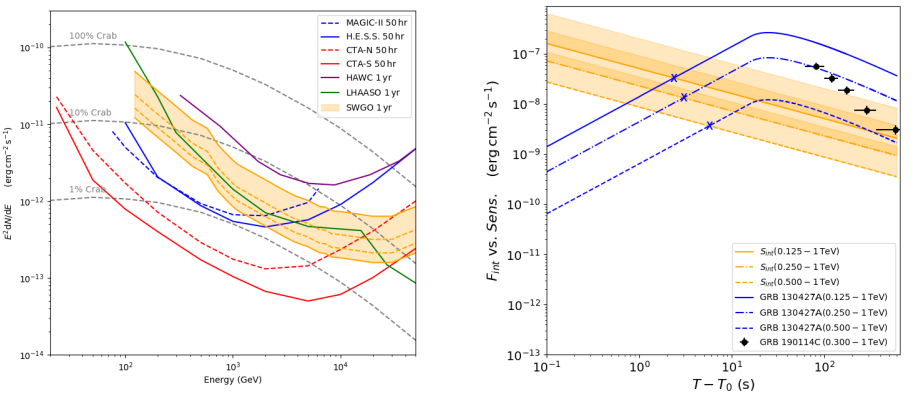

Fig. 3. **Left panel:** Spectral coverage and differential sensitivity of some currently operating and next-generation VHE observatories. The sensitivities are computed for a point-like source at a zenith distance of 20°. Different fractions of the Crab Nebula flux are shown for comparison. The shaded area is the sensitivity range expected for various configurations of SWGO.[36] **Right panel:** The expected integrated flux for a GRB 130427A-like event above 125 GeV, 250 GeV and 500 GeV, compared with the corresponding SWGO expected sensitivities. Crosses mark the estimated detection times. The VHE light curve of GRB 190114C above 300 GeV is also shown.[13]

detector arrays. The main advantage of IACT observatories is that they have excellent angular resolution and background rejection power, achieving the best possible sensitivity. On the other hand, these instruments can only operate during dark time and in clear sky conditions, implying a duty cycle of only $\sim 20\%$. In addition, the small FoV and the consequent need to respond to an external alert with target position information and subsequent re-pointing delay does not allow IACT instruments to cover the early GRB emission regime, where many critical observational constraints are expected by different theoretical models.

Thanks to their larger FoV and to the possibility to operate almost continuously, EAS detector arrays have better chances to cover a GRB and to act as an alert system themselves. The main problems of this solution are that EAS arrays need to be located at high altitudes (> 4500 m a.s.l.), in order to be reached by the particle showers initiated by γ-ray primaries with $E \leq 1$ TeV, and that they need to deal with a strong background of cosmic-ray induced air showers. The sensitivity needed to detect the expected VHE signal of GRBs can be estimated by integrating Eq. (1) in time and in energy, with the observed properties of bright LAT bursts, using known or simulated redshifts. Figure 2 shows an example of such calculation. As it is clearly illustrated by the left panel of Fig. 2, the expected signal is a function of the characteristic burst properties, such has flux, duration, spectral index and redshift, and of the energy band that is covered by the observation. In particular, the amount of flux above 100 GeV is critically affected by redshift, meaning that only bright and relatively nearby events can be detected at larger energies. Taking as reference a limiting flux of $5 \cdot 10^{-9}$ ph cm^{-2} s^{-1}, integrated above 100 GeV for an

observing time of 1000 s, which is a reasonable estimate for an instrument concept based on the SWGO reference design,[36] it is possible to reach the VHE signal expected from GRBs down to 10% the power of the brightest LAT detected event up to $z \approx 0.7$.

The SWGO Collaboration is currently investigating the configuration of a next-generation EAS array, based on Water Cherenkov Detectors (WCD), to be installed at a high altitude site in the Southern Hemisphere. By adopting a detector concept able to trigger on low energy shower particles ($\sim$ 20 MeV), with high temporal resolution ($\sim$ 2 ns), it can be shown that an array of 80 000 m^2 can improve background suppression and achieve very good monitoring sensitivities, below the TeV energy domain.[36] Figure 3 presents an illustration of this concept, compared with other currently operating and planned facilities, together with an example of its expected performance, with respect to the temporal evolution of two GRBs with a detected high energy component. If we define the integrated flux expected in the VHE domain within an observation time T as:

$$F_{int}(T) = \frac{1}{T - T_0} \int_{T_0}^{T} \mathrm{d}t \int_{E_{low}}^{1\,\mathrm{TeV}} E \frac{\mathrm{d}N(t)}{\mathrm{d}E} \mathrm{d}E, \tag{3}$$

where the spectrum is defined through Eq. (1) and Eq. (2), we can easily verify that the times required to detect the incoming fluxes are significantly below 10 s, meaning that such configurations would be particularly effective to react to the early phases of the transient. Given the promising detection chances in case of GRBs with well measured energetic components, SWGO represents an attractive solution to investigate the properties of VHE emission in the early stages of GRBs and, thus, help solving the question of whether an energetic component associated with the burst onset is a common feature of GRBs or a distinguishing property of a specific event class.

4. Conclusions

The systematic investigation of GRBs in the VHE range will cover a fundamental role in the quickly evolving field of Multi-Wavelength and Multi-Messenger Astrophysics. After the first detection of Gravitational Waves (GW), which marked a corner stone in scientific research,[37] the execution of regular monitoring campaigns increased the chances of obtaining multiple detections of fast transients. The associated observation of GW 170817 and of the short GRB 170817A, in particular, represented the first direct evidence of the compact binary merger as a viable explanation to short GRBs and it opened the way to a wealth of cosmological and high energy physics tests.[8,9] A fundamental question related to the nature of GRBs and to their distinction in classes is whether the formation of the jet and its subsequent evolution involve substantial hadronic processes, a matter that could be unambiguously solved by the association of GRBs with neutrino events or with early VHE emission.[38]

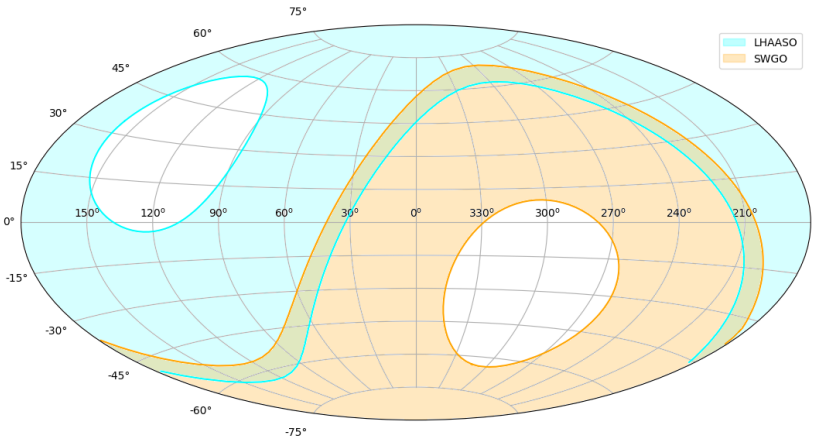

Fig. 4. Representation of the visible sky, within 30° from zenith, showing the sky regions covered by LHAASO (cyan shaded area) and by SWGO, assuming an observatory latitude close to 23° S (orange shaded area). The map is plotted in Galactic coordinates.

Evidence based on existing observations has firmly demonstrated that GRBs can produce energetic radiation and also that this spectral component may be associated with the elusive prompt emission.[17] The observation of early high energy photons, together with hints of the VHE detection of short GRBs, like in the case of GRB 160821B, challenges the external shock model predictions and suggests that additional mechanisms may be at work. Covering the VHE window, particularly in the early emission phase, will be a crucial requirement for the development of more advanced models. The ability to characterise the earliest properties of VHE emission will be fundamental both to improve the time-domain investigation of Multi-Messenger triggers, as well as to offer high quality alerts for follow-up observations that, as demonstrated by H.E.S.S. and further boosted by the upcoming investigations with CTA, can track the VHE evolution up to several hours in the afterglow.[30]

The large FoV and the nearly continuous operating time of EAS arrays make this type of instruments an ideal facility to survey the sky looking for fast transient sources. Their ability to cover large sky areas will help constraining the VHE properties of early GRB emission, with new implications on the involved radiation mechanisms. However, in order to observe events located at cosmological distances, they need to work effectively in the sub-TeV energy domain and, therefore, to be located in high altitude sites. The Large High Altitutde Air Shower Observatory (LHAASO),[39] in the Northern hemisphere, and SWGO, from the Southern hemisphere, have the potential to carry out a VHE monitoring program that will cover a large fraction of the visible sky, as illustrated in Fig. 4. If extended in the sub-TeV domain, this nearly constant scanning of the sky will help clarifying the VHE properties of GRBs by assessing the existence of spectral components that, though

predicted in well justified models, are hard to detect with instruments that need to be triggered and subsequently pointed to the target. In addition, fostering a VHE monitoring ability will offer a new window to identify sources of energetic transients, like gravitational waves and high energy neutrinos. Clearly, the identification of possible counterparts to alerts issued by continuously operating experiments, such as *IceCube* and *LIGO/VIRGO*, will undoubtedly benefit from the existence of a network of VHE monitoring programs, able to detect energetic transients and, thus, to further refine the identification of their sources and their energy production mechanisms.

Since their discovery in the late 1960s Gamma-Ray Burst (GRB) emission has been deeply investigated with the help of the huge amount of data collected covering the entire electromagnetic spectrum. This large and broadband dataset was essential to constitute a general picture describing the GRB physics, revealing the most credible underlying physical processes and environmental conditions ongoing at the GRB site. A key leap in the comprehension of the GRB physics have been achieved recently, thanks to the detection of the newly energetic component in the Very High Energy (VHE, E $>$ 100 GeV) domain. The possible presence of a TeV spectral window in GRBs was predicted and theorized for several decades, but the first observational proofs of its existence were reached only in 2019 thanks to the discoveries claimed by the MAGIC and H.E.S.S. telescopes. GRB190114C was successfully detected in the TeV band by the MAGIC telescopes starting from around one minute after its trigger time and lasting for nearly 40 minutes. A successful follow-up campaign was performed and the multi-wavelength afterglow emission of the event was collected from 1 to about 2×10^{17} GHz. Such very broad dataset allows to perform unique studies on the radiation mechanisms and on the physical properties of such event. In this contribution I will describe the main results and the theoretical interpretations that have been derived from the multi-wavelength dataset of GRB190114C. In particular, the description of the TeV component detected by the MAGIC telescopes as produced via the Synchrotron Self-Compton (SSC) mechanism and its connection with the emission at lower energy bands will be presented. Such studies are a fundamental starting point for the interpretation of the current and upcoming events that will be observed in the VHE domain.

Keywords: Gamma-ray bursts; very high energy; synchrotron-self compton

1. Introduction

Gamma-Ray Bursts (GRBs) are transient phenomena produced during cataclysmic events such as the death of massive stars or the merging of binary compact objects like neutron stars and black holes.

The GRB electromagnetic radiation is characterized by initial rapid and irregular flashes bright in the keV-MeV band, the so-called *prompt* emission phase followed by a long-lasting broadband fainter emission, named *afterglow*. The duration of the prompt emission spans from milliseconds to thousands of seconds and is used to classify GRBs as *short* and *long* with a separation value of 2 s. The afterglow phase, which follows or partially overlaps with the prompt emission, is usually detectable within timescale of days, weeks or in some cases even months.

Because of its multi-wavelength nature, intense campaigns are performed to search for and follow this broadband emission from radio up to γ-rays, both with ground-based telescopes and space-born satellites. While the prompt emission mechanism is still unclear, the afterglow radiation from radio up to GeV is well described as synchrotron emission produced in the external forward shock scenario due to the interaction between the jet and the surrounding interstellar medium or stellar wind (depending on the progenitor). The possible extension of the GRB emission in the high energy (0.5 MeV $<$ E $<$ 100 GeV, HE) and to the very high energy domain (VHE, E $>$ 100 GeV) has always been one of the most debated open questions in GRB physics. The HE observations have revealed the presence of an emission component with peculiar temporal and spectral properties. The highest energy photons observed by Fermi-LAT are hardly to reconcile with the standard synchrotron afterglow scenario and hint the possibility that a new VHE emission component in GRBs is present.

A firm conclusion could be reached thanks to the observations performed by ground-based imaging Cherenkov telescopes. In particular, the MAGIC and the H.E.S.S. telescopes revealed unequivocally the presence of a VHE emission component in GRB afterglows up to TeV energies.[1] Such detections gave birth to unique studies covering several open topics of the GRB physics. In this contribution we report the analysis results and the theoretical implications derived from the TeV detection of GRB 190114C performed by the MAGIC telescopes. The interpretation of the full GRB 190114C multi-wavelength dataset with the synchrotron and Synchrotron-Self Compton (SSC) scenario and the intimate connection between the TeV emission component and the lower energy ones is presented.[2,3]

2. TeV detection and interpretation of GRB 190114C

GRB 190114C is a long GRB triggered by Swift-BAT and Fermi-GBM space instruments on 14 January 2019, 20:57:03 UT (hereafter T_0). The event was detected also by several other space instruments, namely Fermi-LAT, Swift-XRT, Swift-UVOT, AGILE, INTEGRAL/SPI-ACS, Insight/HXMT, and Konus-Wind. Triggered by space satellite alerts, the event was then followed-up and detected by

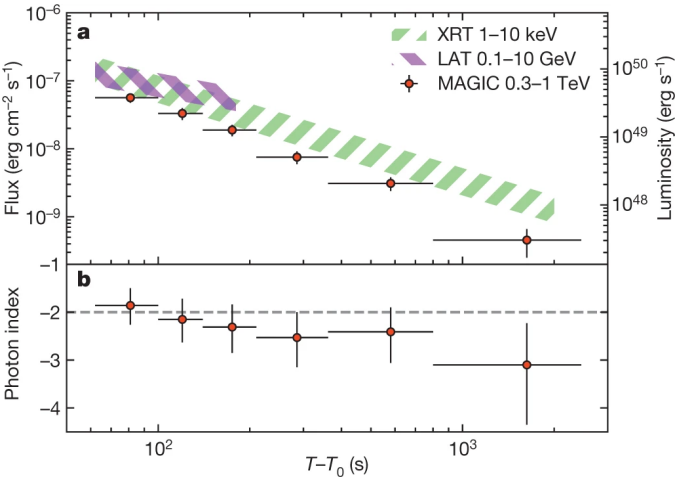

Fig. 1. **a**: MAGIC (red circles), XRT (green band) and LAT (red band) light curves. **b**: temporal evolution of the intrinsic spectral photon index.[2]

the MAGIC telescopes in the VHE band and several optical-NearInfraRed (NIR) and radio ground based telescopes. The Nordic Optical Telescope and the Gran Telescopio Canarias gave a redshift estimation of $z = 0.4245 \pm 0.0005$.

The timeline of the MAGIC observation can be described as follows:

- the Swift-BAT alert was received by the MAGIC automatic alert system at $T_0 + 22$ s. The alert was validated, the event tagged as observable and the automatic fast repositioning procedure started;
- the telescopes reached the target and started tracking at $T_0 + 50$ s;
- the data acquisition started receiving the first events at $T_0 + 57$ s and operated stably from $T_0 + 62$ s;
- observation lasted until $T_0 + 15912$ s when a zenith angle of 81.14° was reached.

The observation was performed in good weather conditions and in presence of the Moon, resulting in a night sky background approximately 6 times higher than the standard dark night conditions.

The analysis of the MAGIC dataset was performed with unprecedented accuracy performing many checks and tests to investigate the behaviour of the subsystems during the repointing and data taking. Moreover, several dedicated MC sets were produced in order to match the GRB observational conditions in the most precise way. The result of the offline analysis shows a clear detection above the 50 sigma level in the first 20 minutes of observation.

The light curve for the intrinsic flux corrected for the Extragalactic Background Light (EBL) absorption in the 0.3–1 TeV range was derived. A comparison of this light curve with the simultaneous X-ray and HE emission is shown in Figure 1.

From the evolution of the light curve and the comparison with the lower energy band emission it is possible to derive clues on the origin and the amount of power radiated in the TeV component. The TeV light curve is well described with a simple power-law temporal decay with index $\beta = 1.60 \pm 0.07$. A similar behaviour can also be seen in the X-ray and HE band. These properties, together with the absence of breaks, cutoffs or irregular variability, support the conclusion that the observed VHE emission component belong to the afterglow phase. Nevertheless, the presence of a subdominant prompt component cannot be excluded.

The comparison of the simultaneous light curves shows also that the radiated power in the TeV band is mostly comparable, within a factor of about 2, with the X-ray and HE bands. This means that a non-negligible fraction of energy is radiated in the TeV band. A rough estimate, calculated assuming that the onset of the afterglow is at $T_0 + 6$ s[4] and following the time evolution estimated by the MAGIC light curve is of around $\sim 10\%$ of the isotropic-equivalent energy of the prompt emission E_{iso}.

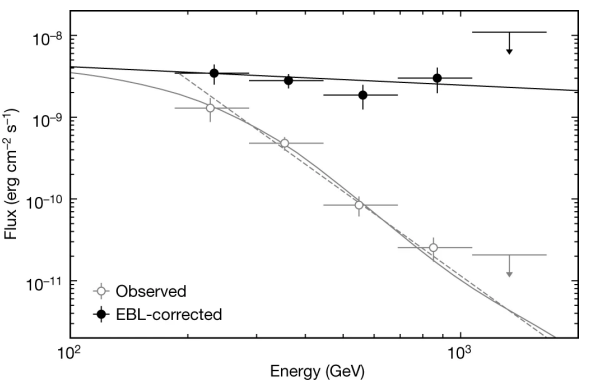

Fig. 2. GRB 190114C Observed (grey open circles) and intrinsic (black filled circles) spectral energy distribution in the time interval $T_0 + 62$ s and $T_0 + 2454$ s. The best fit power-law functions (black solid line and dashed grey line) and the EBL attenuated curve (solid grey line) are also shown.[2]

In Figure 1 also the temporal evolution of the intrinsic spectral photon index α_{int} of the TeV differential photon spectrum is shown. A constant value of $\alpha_{int} \approx -2$ is consistent with the data, considering the statistical and systematic errors. As a result, throughout the MAGIC observation, no spectral variability can be claimed. This value indicates that the radiated power is equally distributed in the 0.3-1 TeV energy range.

The observed and EBL-corrected spectral energy distributions in the 0.2-1 TeV energy range and ($T_0 + 62$ s - $T_0 + 2454$ s) time interval were also derived. Both the spectra are fitted with a simple power-law with indices $\alpha_{obs} = -5.34 \pm 0.22$ and $\alpha_{\rm int} = -2.22^{+0.23}_{-0.25}$ respectively for the observed and EBL-corrected spectrum.

This result states that the VHE component observed by MAGIC is extended up to TeV energies. Moreover, the steep observed spectrum obtained certificates the strong effect of the EBL absorption (a factor of ~ 300 at 1 TeV) in shaping the GRB spectra in the VHE domain.

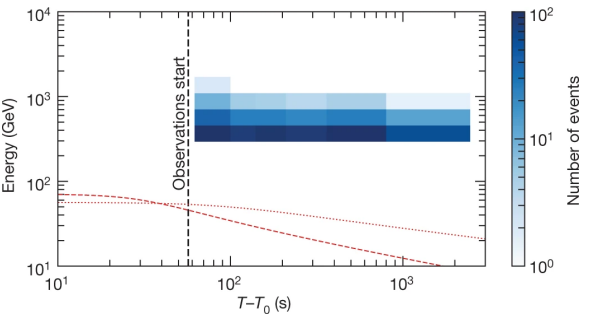

Fig. 3. Distribution of the number of GRB 190114C γ-ray events observed by MAGIC binned in time and energy and colour-coded. The synchrotron burnoff limiting curves are also displayed with two different assumptions for the external medium surrounding the GRB site: constant-density interstellar medium (dotted curve) and wind-like scenario (dashed curve).[2]

The similarities observed between the X-ray and the TeV light curves point towards the possibility that the same radiation mechanism is responsible for both components. Nevertheless, we proved that the TeV component cannot be interpreted as a simple extension in energy of the electron synchrotron emission mechanism. Indeed, in this scenario the energy of the accelerated electrons and hence of the synchrotron photons emitted is limited to a maximum value. This value can be estimated by equating the acceleration timescale and the synchrotron losses timescale, which dominates the electron energy losses. As a result, the maximum synchrotron photon energy, also called *synchrotron burnoff limit* is estimated as $E_{\mathrm{syn,max}} \sim 0.1\Gamma_{\mathrm{b}}(t)/(1+z)$ GeV where $\Gamma_{\mathrm{b}}(t)$ is the Lorentz bulk factor of the GRB jet and z is the redshift. In Figure 3 we compared the energy of the observed photons by MAGIC binned in time and energy with $E_{\mathrm{syn,max}}$ assuming two possible scenarios for the dynamical evolution of the GRB blast wave. It can be clearly seen that events detected by MAGIC are well more energetic than $E_{\mathrm{syn,max}}$ in both scenarios. This gives a strong proof that a different radiation mechanism than electron synchrotron radiation must be claimed to explain such VHE emission component in GRB 190114C.

3. Multi-wavelength afterglow modeling

A multi-wavelength interpretation is fundamental for an in-depth study of the properties of the TeV emission and its connection with the lower energy band radiation. GRB 190114C emission was detected across 17 orders of magnitude in energy and

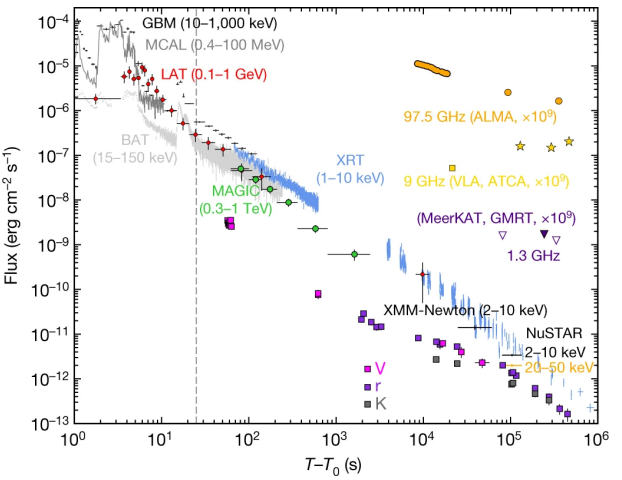

Fig. 4. Broadband light curves of GRB 190114C. Data from radio up to γ-rays are included. The vertical dashed line marks approximately the end of the prompt phase, identified as the end of the last flaring episode.[3]

by more than 20 instruments both from ground and in space (see Figure 4). In particular, the simultaneous data collected in a few time intervals in the X-ray (XRT, BAT, GBM), HE (LAT) and VHE (MAGIC) domain allow to build multi-wavelength time-binned spectra (see Figure 5). In the first time interval (68-110 s) the usual synchrotron peak flux is located in the X-ray band. Subsequently, in the HE band a decreasing flux behaviour is observed. Then, the VHE data implies the presence of a second peak in the flux and a spectral hardening for energies $E > 0.2$ TeV. This behaviour can be explained only if we assume that the TeV emission is not an extention of the X-ray synchrotron emission component but it is produced by a different radiation mechanism.

The most credible scenario able to describe consistently the multi-wavelength data is the *synchrotron and SSC external shock scenario*. In this picture, the SSC radiation mechanism produces the TeV photons while the synchrotron emission can explain the lower energy band radiation. The distribution of accelerated electrons emitting the synchrotron radiation are also responsible for the up-scattering of the same synchrotron photons through inverse Compton mechanism. As a result, a second spectral component peaking in the VHE band is generated. The afterglow emission is usually well described through external shocks. SSC radiation at TeV level can be also produced in internal shock synchrotron models for the prompt emission. However, for GRB 190114C it was estimate that it can only partially contribute ($\lesssim 20\%$) for the flux emitted at early times ($\lesssim 100$ s). As a result, the SSC radiation in the afterglow scenario is the most viable process.

The validity of this scenario was tested thanks to a numerical modeling. The full multi-wavelength dataset was modelled with a numerical code reproducing the

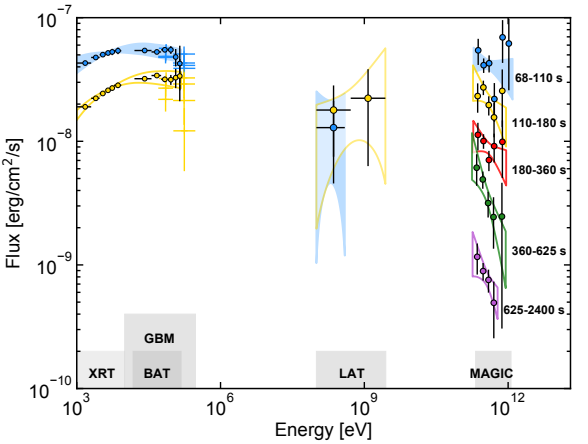

Fig. 5. Multi-band SEDs in five different time intervals. MAGIC data analysis results are corrected for the EBL attenuation. MAGIC and LAT contour regions are drawn from the 1σ error of their best-fit power-law functions. For Swift data, the regions show the 90% confidence contours for the joint fit for XRT and BAT, obtained by fitting a smoothly broken power law to the data.[3]

synchrotron plus SSC radiation emitted in the external forward shock afterglow scenario. In Figure 6 the modeling for two time intervals and for the X-ray, HE and VHE bands is shown. The numerical code solves the time-evolving electron distribution and calculates the corresponding photon emission covering the entire electromagnetic spectrum. The following radiation processes are considered: electron synchrotron emission and self-absorption, SSC emission, adiabatic losses, γ-γ absorption and emission from pairs. A set of inputs parameters containing some assumptions due to unknown properties of the acceleration process, of the shock microphysics, of the external medium and of the GRB jet and the initial conditions of the system are given in the code. The soft spectrum derived from the MAGIC dataset constrain the peak of the SSC component to be below 200 GeV. Such condition is obtained assuming that the SSC process is in Klein-Nishina regime and the γ-γ internal absorption has a non-negligible contribution in shaping the higher energy tail of the VHE spectrum.

Acceptable modeling of the multi-wavelength afterglow spectra have been found with an initial isotropic-equivalent kinetic energy of the blastwave $E_k \gtrsim 3 \times 10^{53}$ erg. The electron and magnetic field equipartition parameters are respectively $\varepsilon_e \approx 0.05-0.15$ and $\varepsilon_b \approx 0.05-1\times10^{-3}$, the density of the external medium is $n \approx 0.5-5$ cm^{-3} and the distribution of the accelerated electrons is described with a power-law of index $p \approx 2.4-2.6$. This set of values for the GRB afterglow parameters is similar to the one used for past GRB afterglow studies at lower frequencies. This is an indication that the SSC component can be a relatively common process for GRB afterglows.

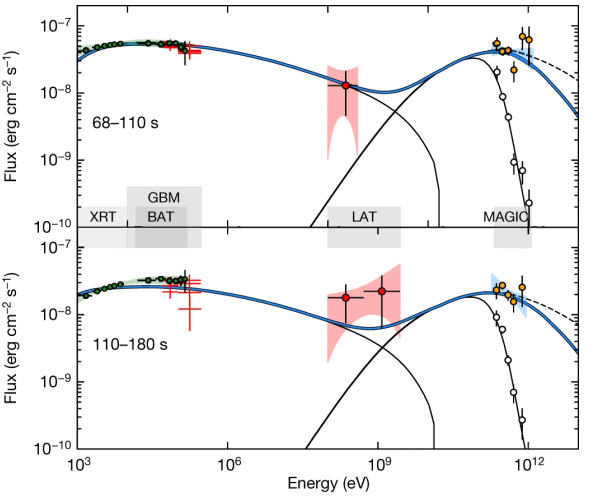

Fig. 6. Modeling of GRB 190114C spectral energy distributions in two different time intervals. Observed (thin solid line) and deabsorbed (thick blue line) spectrum are displayed. The dashed line is the SSC component neglecting the effects of internal γ-γ opacity.[3]

4. Conclusions

Observation and detection of GRB 190114C is a key milestone for the study and the interpretation of GRB physics. After decades of searches, the unambiguous discovery of a TeV component in GRBs made it possible to address for the first time ever several open questions. The newly open TeV spectral window also gives rise to new challenges for the observation and interpretation of GRBs.

A complete multiwavelength modeling of the GRB 190114C data covering the entire electromagnetic spectrum from radio up to TeV was presented. The full evolution of the afterglow emission was interpreted with the synchrotron plus SSC external forward shock scenario. The afterglow parameters used in the modeling of the X-ray, HE and VHE data have relatively common values, similar to those used in previous studies on GRBs where VHE emission was not detected. When evolving this solution to later times (see Figure 7) the optical and radio emission is overpredicted with respect to the observations. This inconsistency between the data and the modeling can be interpreted as an indication that some of the fixed parameters of the afterglow theory (e.g. the electron and magnetic field equipartition parameters) may evolve in time.

The intrinsic properties of GRB 190114C are not so exceptional when compared with the sample of the observed long GRBs. Despite being an energetic event (the isotropic-equivalent energy from the prompt is $\approx 3 \times 10^{53}$), it lies in the highest 30% distribution in energy for long GRBs.[5] This suggests that a larger sample of GRBs can have a detectable TeV component. On the other hand, favourable observational conditions and redshift play a crucial role in order to make TeV detections possible.

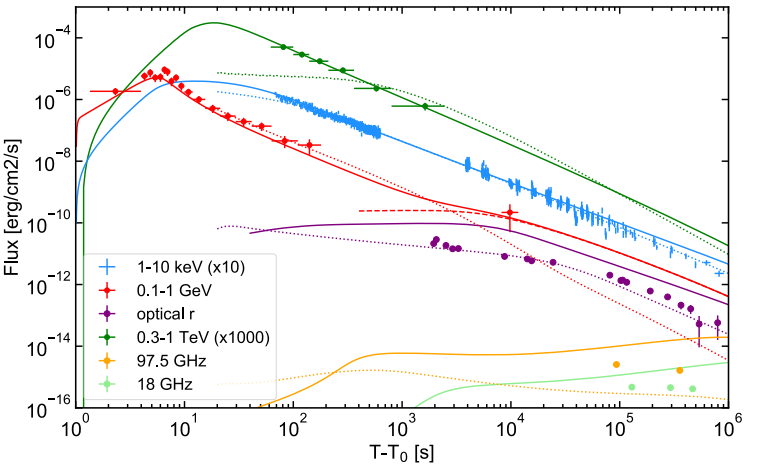

Fig. 7. Modeling of GRB 190114C afterglow light curves from radio up to TeV. Two different sets of parameters, respectively displayed in solid and dotted lines are compared to the observations. The former one is optimized for the X-ray, GeV and TeV data while the latter one well reproduces the late time optical modeling but do not explain the early time TeV emission. The dashed red line indicate the SSC contribution in the 0.1-1 GeV band.[3]

This was proved by the TeV detections of other three long GRBs: GRB 180720B,[6] GRB 190829A[7] and GRB 201216C.[8] These discoveries showed that TeV detections can be possible even at late times (hours on even a day after the trigger like in the case of GRB 180720B and GRB 190829A), or in low-luminosity events ($E_{iso} \approx 3 \times 10^{50}$ in GRB 190829A), or at higher redshift ($z = 1.1$ for GRB 201216C). The first population studies of GRBs at VHE will provide the possibility to investigate the conditions which favour a TeV detection.

The TeV photons detected from GRB 190114C were also used to give insights on some fundamental physics questions. An example is given by the study and the bounds derived on the Lorentz invariance violation effect.[9]

Furthermore, the ongoing observations of GRBs in the VHE domain will be fundamental to state the presence of a TeV emission component in short GRBs (a hint of detection, but still not conclusive, was claimed for GRB 160821B[10]) or during the prompt emission phase. Short GRBs are known to be linked with gravitational wave events. Therefore, the detection of a TeV emission component could give information on the structure of GRB jets as well as on the geometry of the merger event. The detection of TeV emission in the prompt emission phase shall provide essential information on the radiation mechanisms involved which are still unknown.

Further detections of GRBs in the VHE domain will be also useful to test the current most credible scenario for the TeV afterglow emission, namely the SSC external forward shock scenario. At the current stage, the results published for GRB 190114C,[3] GRB 180720B[6] and GRB 190829A[11] can be satisfactorily interpreted with the SSC scenario. Nevertheless, several open questions and assumptions

on the acceleration process, shock microphysics and environmental condition are still unclear.

In this evolving context the robust results obtained from the analysis and the interpretation of GRB 190114C will be a reference point for future studies of the properties of the VHE emission component in GRBs.

AGILE and GRBs: 13 years of observations

A. Ursi*, on behalf of the AGILE Team
INAF/IAPS, via del Fosso del Cavaliere 100, I-00133 Roma (RM), Italy
**E-mail: alessandro.ursi@inaf.it*

Over a time frame of 13 years, from November 2007 to November 2020, the AGILE MiniCALorimeter (MCAL; 0.4-100 MeV), detected 503 Gamma-Ray Bursts (GRBs). This sample is constituted by 44% short GRBs and 56% long GRBs, as retrieved from the study of the associated T_{50} and T_{90} burst duration distribution. For 258 GRBs, it was possible to perform a spectral analysis by adopting a single power law model; for 43 of them, also a spectral fit with a Band model with peak energy E_p above 400 keV was possible. More than 90% of these bursts were also detected by the AGILE Scientific RateMeters (RMs), providing comprehensive simultaneous observations from few tens keV to 100 MeV. The MCAL GRBs mostly consists of short-duration, spectrally hard events, due to the energy range of the detector and the adopted onboard trigger configurations, representing a burst sample which can be used to provide further insights on the high-energy component of hard-spectrum bursts.

Keywords: GRBs, high-energy, catalog, AGILE

1. Introduction

Discovered in the late 1960s,[1] Gamma-Ray Bursts (GRBs) still represent an intriguing and not completely understood phenomenon. These events consist of transients bursts of hard X- and gamma-rays, emitted by ultra-relativistic particles which have been accelerated in extragalactic central engines, releasing isotropic energies of about $E_{iso} \gtrsim 10^{51} - 10^{52}$ erg.[2] On the basis of their spectral hardness and time duration, GRBs are usually divided in short GRBs, lasting less than ~ 2 s and exhibiting a hard spectrum up to MeV energies, and long GRBs, lasting more than ~ 2 s and exhibiting a softer spectrum. The first ones are produced by the merger of binary neutron stars (BNS),[3–7] whereas the second ones are associated with Type Ic core-collapse supernovae.[8,9]

2. The AGILE satellite

The Astrorivelatore Gamma ad Immagini LEggero (AGILE) is an Italian space mission for high-energy astrophysics.[10] Its payload consists of a tungsten-silicon imaging tracker, sensitive in the 30 MeV - 50 GeV energy range, a non-imaging CsI(Tl) scintillation MiniCALorimeter (MCAL), sensitive in the 0.4-100 MeV energy range, a coded mask X-ray imager SuperAGILE (SA), sensitive in the 18-60 keV energy range, and an Anti-Coincidence (AC) system, sensitive in the 50-200 keV energy range. The suite of silicon tracker and MCAL detectors constitute the Gamma-Ray Imaging Detector (GRID).

Starting 2009, the satellite underwent a failure of the reaction wheel, losing the possibility to point sources in the sky and starting to spin around the sun-pointing axis, with an angular velocity of 1 rotation / 7 min. Spinning does not represent an issue for the MCAL detector, due to its ideal 4π sr FoV; moreover, it does not affect GRB detection, given the isotropic nature of these events. However, spinning could have an effect for what concerns spectral analysis of long GRBs, as such long-lasting events would be detected under different angles, throughout their whole duration, requiring the retrieval of several response matrices, and making the spectral fit more complex.

2.1. *MCAL and scientific ratemeters*

The AGILE Mini-CALorimeter (MCAL)[11, 12] is a non-imaging scintillation detector, sensitive between 400 keV and 100 MeV, composed of 30 CsI(Tl) scintillator bars. MCAL is a self-triggered detector, issuing a data acquisition with 2 μs time resolution whenever a count rate exceeding a given threshold is encountered. The trigger system acts on different trigger logic timescales: in particular, the so-called "hardware" logic works on short-duration timescales (0.293 ms, 1 ms, 16 ms) and adopts a static trigger with a fixed threshold count rate required to issue a data acquisition, whereas the so-called "software" logic works on longer-duration timescales (64 ms, 256 ms, 1024 ms, and 8192 ms) and adopts an adaptive trigger with a threshold count rate dependent on the background rate.

For what concerns the detection of GRBs, differently from the silicon tracker and SuperAGILE, MCAL does not require these events to lay within a given FoV, allowing a continuous monitoring of an ideal $\sim 4\pi$ sky. Moreover, MCAL focuses on the poorly investigated tens of MeV energy range, allowing to provide insights on the high-energy component of hard-spectrum bursts.

A first MCAL GRB Catalog with 84 events detected in the first two years of the AGILE mission, in the so-called "pointing mode" (2007-2009), was released in 2013[13] and a second MCAL GRB Catalog with 503 events, covering also the successive 11 years in the so-called "spinning mode" (2007-2020) was recently submitted to ApJ.[14] MCAL is part of the 3rd Inter-Planetary Network (IPN), providing GRB detections which can be used for triangulation and localization of the bursts. Starting 2017, a new real time pipeline system has been established, for the automatic offline analysis of MCAL data and the prompt delivery of GCN Notices and Circular to the scientific community, in case of a transient detection ([a]). In recent years, the onboard trigger configuration was modified to increase the MCAL detection efficiency to short-duration transients, in order to improve the detector sensitivity to possible electromagnetic counterparts of gravitational wave events, during the LIGO-Virgo observational runs O2 and O3, and in order to save onboard mass memory, to deal with severe telemetry restrictions undergone in recent years.

[a] https://gcn.gsfc.nasa.gov/agile_mcal.html

The MCAL, SA, and AC data are continuously recorded in telemetry as scientific RateMeter (RM) data, with a 0.5 s (for SA) and 1.0 s (for MCAL, and AC) time resolution, to provide a monitoring of the X- and gamma-ray background modulation throughout the satellite orbital phases. Nevertheless, the AGILE RMs allow to independently detect a large number of high-energy transients, as GRBs, Soft Gamma-ray Repeaters (SGRs), or solar flares. Despite the coarse time resolution, RM data might serve as back-up of data acquired by the onboard detectors, as well as to provide cross-check and validation of GRBs detected by MCAL.

3. Methods

A cross-search between $\sim 10^6$ AGILE MCAL triggers, issued onboard from November 2007 to November 2020, and $\sim$ 4500 IPN[15] bursts (IPN webpage:[b]), reported by the network in the same time interval, lead to the identification of 476 GRBs in the MCAL data. Due to the better efficiency of MCAL to detect short-duration transients, 109 long GRBs were only partially acquired onboard by the detector. Despite being incomplete, these events may serve as further detections which can be used to improve sky localizations via triangulation.

A parallel blind search in the MCAL data, using the offline burst search algorithm,[16] led to the detection of other 27 candidate short GRBs, not reported by other space missions. The total MCAL GRB sample is therefore constituted by 503 bursts, as reported in the second AGILE MCAL GRB Catalog,[14] recently submitted to ApJ and available on line on the ASI Space Science Data Center (SSDC) web portal at[c]. About 90% of these events have been also detected by one or more scientific RMs. A simultaneous detection of all scientific RMs would provide a broad band characterization of these events, from few tens keV to tens of MeV. In particular, the RMs detection is very suitable when dealing with partially acquired long GRBs, in order to reconstruct the whole light curve of the event and provide insights in different wavelengths.

3.1. *Time analysis*

For the 394 fully detected GRBs, it was possible to reconstruct the complete light curves of the events and to study their temporal properties. The T_{50} and T_{90} time distributions[17] of these bursts ended up with 173 short GRBs and 221 long GRBs, as shown in Fig. 1. The sample shows a large fraction (44%) of short GRBs, with respect to that retrieved by other space missions, as INTEGRAL,[18] Fermi GBM,[19] and Konus-Wind.[20] This can be ascribed to different reasons: first of all, the onboard trigger configuration optimized for the detection of short-duration transients, as already exposed in Section 2.1; the second reason is related to the relatively high-energy ($>$ 400 keV) range of MCAL, which makes the detector more sensitive

[b] http://www.ssl.berkeley.edu/ipn3/
[c] https://www.ssdc.asi.it/mcal2grbcat/

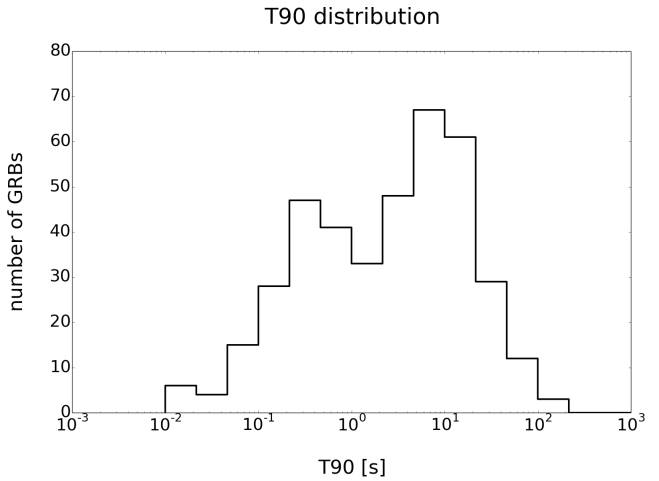

Fig. 1. T_{50} and T_{90} distributions of 394 GRBs fully detected onboard by MCAL. The typical bimodal distribution consists in 44% short GRBs and 56% long GRBs.

to hard-spectrum bursts, typically short GRBs. Moreover, the 0.4-100 MeV energy range allows to investigate only a limited spectral component of the detected bursts: a GRB will typically last longer if considering the whole spectrum including also the keV - tens of keV energy range. An example of this is shown in Fig. 2, where the same burst, GRB 200829A, is detected by the SA and the MCAL RMs, and the event clearly exhibit a longer time duration in the softer SA regime (15.3 ± 0.5 s), with respect to that observed in the harder MCAL regime (8.1 ± 0.5 s). The SA light curves have been rescaled in order to have similar background rates and to better highlight the time duration difference in the two energy ranges.

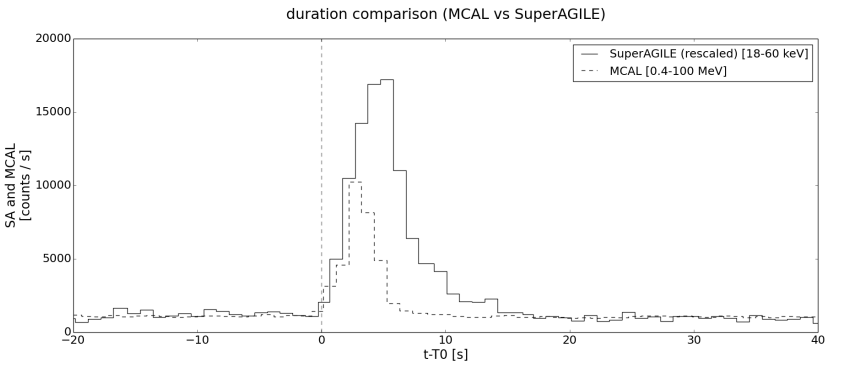

Fig. 2. GRB 200829A as detected by SuperAGILE, in the 18-60 keV energy range, and by MCAL, in the 0.4-100 MeV energy range. The event clearly lasts longer (15.3 ± 0.5 s) in the softer energy range, with respect to the MCAL high-energy range (8.1 ± 0.5 s). Data are rescaled in order to have similar background rates and highlight the time duration difference.

3.2. *Spectral analysis*

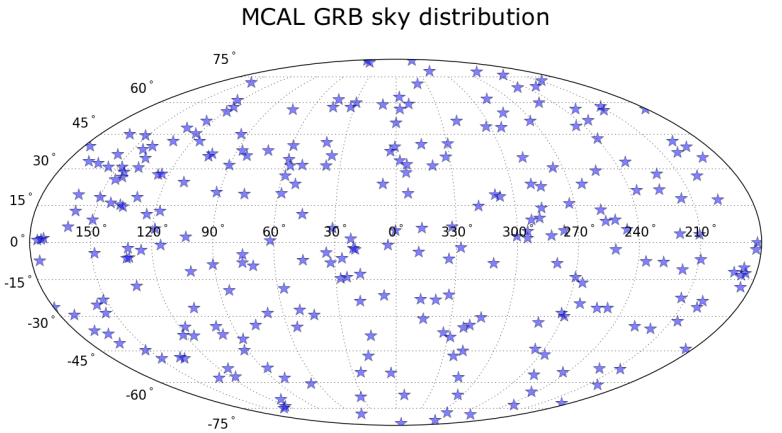

Fig. 3. Sky distribution of 276 MCAL GRBs, for which it was possible to retrieve an external localization from other space missions, or from IPN triangulations. Among them, 258 events could be fitted with a single power law model, and 43 events could be fitted also with a Band model.

In order to perform spectral analysis of the MCAL GRBs, it is necessary to retrieve the corresponding sky localizations, in order to reconstruct the appropriate response matrix of the instrument at the time of the detection. As MCAL is a non-imaging detector, localizations were retrieved from other space missions with imaging capabilities, or from IPN triangulations. In particular, it was possible to retrieve the sky localization of 276 GRBs of the MCAL sample, from detections by Fermi GBM, Fermi LAT, Swift BAT, Swift XRT, INTEGRAL ISGRI, or IPN triangulations. The spatial distibution of these events is shown in Fig. 3. Exploiting these localizations, on the basis of the available count statistics, it was possible to carry out a spectral fit for 258 GRBs. Spectral analysis was carried out using the XSpec package (version 12.9.0[21]), and adopting different fitting statistics depending on the count and background rates. Spectral fit was carried out in the fixed energy range from 400 keV to 50 MeV.

For 258 GRBs, a spectral fit with a single power law model was possible. The average photon index obtained from this sample is equal to $\langle\beta\rangle \sim -2.3$, highlighting the hardness of these bursts. The distribution of the power law photon index is shown in Fig. 4. The MCAL GRB fluxes, obtained from the spectal fitting with a power law model and estimated with a 90% confidence level, range between $3.9 \cdot 10^{-7}$ erg cm^{-2} s^{-1} and $1.0 \cdot 10^{-2}$ erg cm^{-2} s^{-1}, whereas the corresponding fluences, integrated over the related T_{90} time durations, range from $5.5 \cdot 10^{-8}$ erg cm^{-2} and $1.3 \cdot 10^{-2}$ erg cm^{-2}. The distribution of GRB fluxes is reported in Fig. 5. Moreover, for 43 particularly hard GRBs, it was possible to obtain a good spectral fit also by adopting a Band model[22] with peak energy $E_p > 400$ keV. In particular, these events

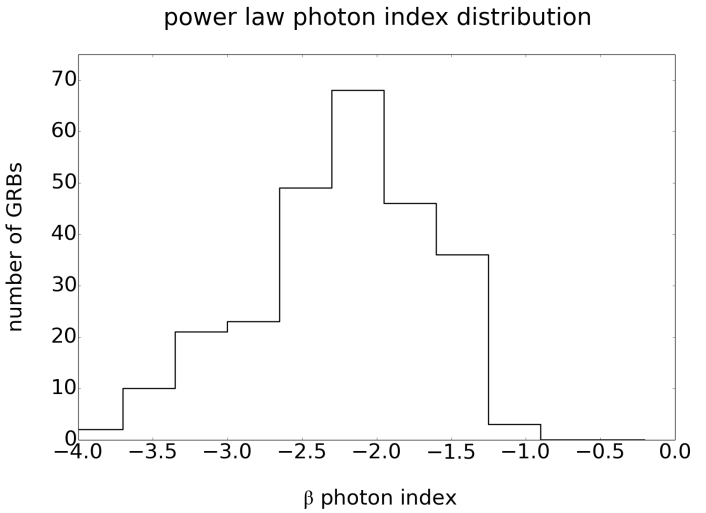

Fig. 4. Distribution of the photon index β of the single power law adopted to fit 258 MCAL GRBs. The average photon index results equal to $\langle\beta\rangle \sim -2.3$.

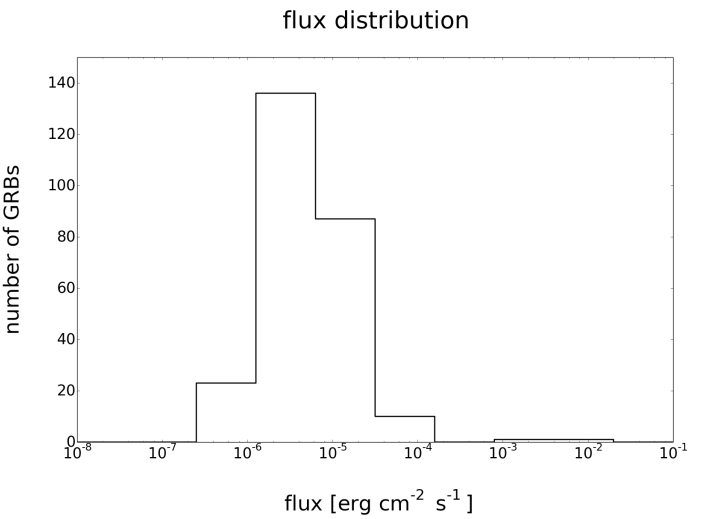

Fig. 5. Distribution of the GRB fluxes, in the 0.4-50 MeV energy range, obtained by fitting 258 burst with a single power law model.

exhibit a mean low-energy photon index $\langle\alpha\rangle \sim -0.6$, a mean high-energy photon index $\langle\beta\rangle \sim -2.5$, and a mean peak energy $\langle E_p\rangle \sim 640$ keV. The distribution of the high-energy photon index β resulting from the fit with a Band model is shown in Fig. 6.

It is interesting to notice that 92 GRBs can be fitted with power laws with photon indices $\beta > -2$, which correspond to hard-spectrum events with spectral

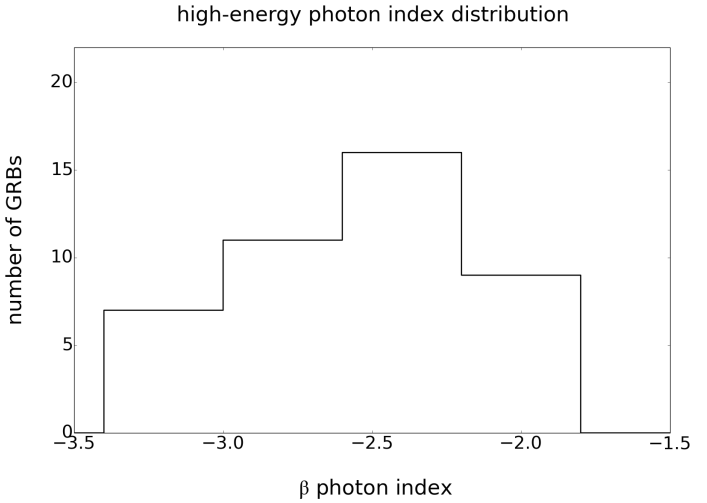

Fig. 6. Distribution of the high-energy photon index β of the Band model adopted to fit 43 MCAL GRBs. The average photon index results equal to $\langle\beta\rangle \sim -2.5$.

energy densities νF_ν with positive slopes, extending the emission up to the highest energies. These events and the 43 bursts fitted with Band models with $E_p > 400$ keV represent the hardest spectrum GRB subsample detected by the AGILE MCAL. Among them, 20 events have a simultaneous Fermi LAT detection.

3.3. *GRB population decline and Amati relation*

Adopting fluxes retrieved by spectral fits with power law model, an MCAL GRB $logN - logF$ brightness distribution can be reconstructed, as shown in Fig. 7. Such distribution provides information on the intrinsic spatial properties of GRBs and on the GRBs population decline at large distances. As MCAL is an all-sky monitor, the $logN - logF$ is not affected by on-axis area variations. Issues which can limit the monitoring of the sky, such as passages into the South Atlantic Anomaly, where the detector is switched off, or Earth occultations, which constantly hide about 35% of the available sky, can be neglected over a time frame of 13 years. The deviation at faint fluxes from a -3/2 slope, retrieved at large fluxes and typical of a Euclidean universe, makes the spatial distribution of GRBs unconsistent with a homogeneous universe.

For 8 events out of the 43 MCAL GRBs fitted with a Band model with $E_p >$ 400 keV it was possible to retrieve the corresponding redshift, provided by X-ray or optical observations of their afterglow. Using a standard cosmological model with $H_0 = 67.3$ km s^{-1} Mpc^{-1}, $\Omega_M = 0.315$, and $\Omega_\Lambda = 0.685$, it was possible to evaluate the GRB related rest-frame parameters, such as the intrinsic peak energy $E_{p,i} = (1 + z)E_p$ of the time integrated spectrum and the isotropic equivalent

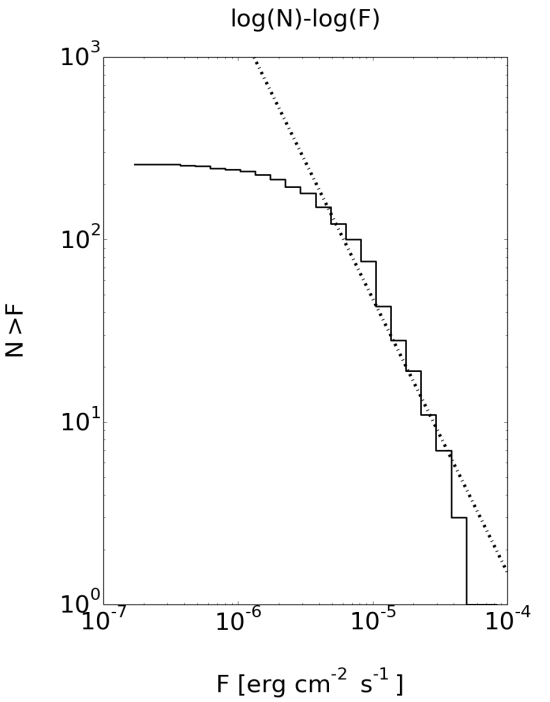

Fig. 7. GRB population decline obtained from the $logN - logF$ distribution of 258 MCAL bursts, fitted with a power law model. For faint fluxes, the brightness distribution departs from a $-3/2$ slope (dash-dotted line), typical of a Euclidean three-dimensional space, making the GRB spatial distribution not consistent with a homogenoeus universe.

energy E_{iso} in the 1-10000 keV energy range. The Amati relation[23,24] obtained from this sample results in a best-fit of the $E_{pi} = K(E_{iso}/10^{52})^m$ curve with a slope $m = 0.130 \pm 0.067$, as shown in Fig. 8. The coefficient obtained for MCAL GRBs is slightly more gentle with respect to the typical value of $m \sim 0.45$ reported by other space missions, due to the due to the non-uniform spectral hardness of the analyzed sample.

4. Conclusions

In more than 10 years activity, the AGILE MCAL detected 503 GRBs in the 0.4-100 MeV energy range. About 90% of these events were also simultaneously detected by the AGILE scientific RMs, covering a wide energy range, from 20 keV to 100 MeV. For 394 events, it was possible to reconstruct the T_{50} and T_{90} durations, ending up with 44% short GRBs and 56% long GRBs, resulting in a large fraction of short-duration bursts. 476 of these events are confirmed by simultaneous detections by other space missions, as reported by the IPN network, whereas 27 of these events are GRB candidates, so far only reported by MCAL. Using localizations provided

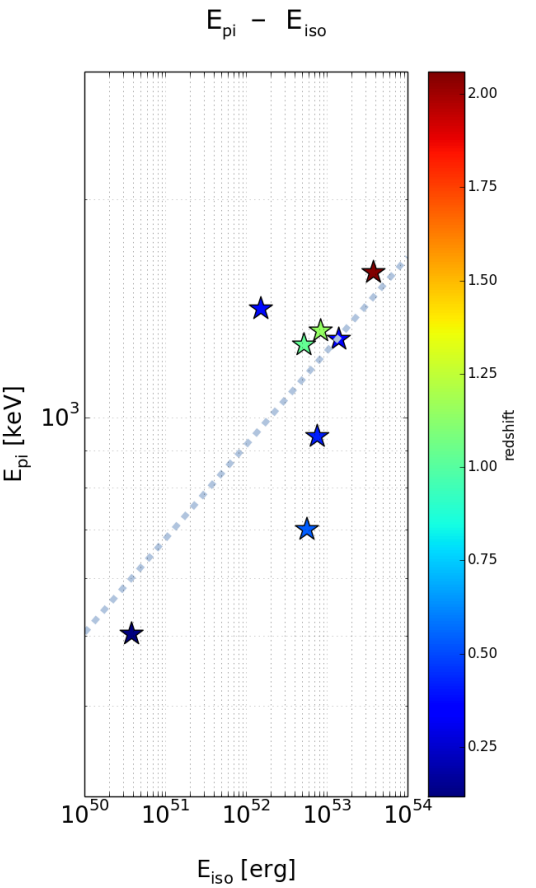

Fig. 8. Rest-frame $E_{iso} - E_{p,i}$ plane with 8 MCAL GRBs with known redshifts (colorbar), fitted with a Band model with $E_p > 400$ keV, in the 1-10000 keV energy range. The dashed line corresponds to the best-fit Amati relation, with slope $m = 0.130 \pm 0.067$.

by other missions, or by IPN triangulations, it was possible to carry out a spectral analysis of the time integrated spectrum for 258 GRBs. In particular, these events are well fitted by a single power law model, with a mean photon index $\langle\beta\rangle \sim -2.3$. For 43 events, also a Band model with peak energy $E_p > 400$ keV provided a good fit. The large fraction of bursts with durations $T_{90} < 2$ s and fittable either with power laws with photon index $\beta > -2$ or with a Band model indicates that MCAL GRBs mainly consists in short-duration, hard-spectrum bursts, which constitute an interesting and suitable sample that can be used to better investigate events with high-energy spectral components in the tens of MeV energy range.

Searching for Gamma-Ray Bursts with the High-Altitude Water Cherenkov (HAWC) observatory

K.L. Engel* for the HAWC Collaboration

Department of Physics, University of Maryland, College Park; 4150 Campus Dr, College Park, MD, USA 20742

**E-mail: klengel@umd.edu*

Satellites and imaging atmospheric Cherenkov telescopes (IACTs) have shown that gamma-ray bursts (GRBs) are capable of producing very-high-energy photons— most notably GRB 190114C, observed up to 1 TeV by the MAGIC telescopes approximately one minute after triggering the Fermi GBM and Swift BAT satellites. Particularly suited to such searches and follow-up studies is the High-Altitude Water Cherenkov (HAWC) Observatory, which monitors 1/6th of the sky at any one time, complementing the pointed observations of TeV telescopes. It covers 2/3rds of the sky every day, with near continuous uptime. The HAWC GRB program comprises two dedicated analyses: a self-triggered all-sky search and a rapid response follow-up of GRBs reported by satellites. Both methods are performed in real time at the HAWC site and additionally repeated on archival data with improved calibration and reconstruction algorithms. Recent upgrades have HAWC poised for detection of the highest-energy gamma rays associated with GRBs, which are key to developing GRB emission models as well as constraining possible beyond-the-Standard-Model physics.

Keywords: Instrumentation: detectors; gamma rays: general; gamma ray burst: general

1. Introduction

Gamma-ray bursts (GRBs) remain one of the most enigmatic astrophysical sources, with the potential to shed light on topics at the forefront of the field, including physics beyond the Standard Model. Measurements of the highest-energy gamma rays associated with GRBs are key to developing models of the relativistic jets powering emission.[1] This is because observations of a spectral cutoff at the highest photon energies can be interpreted as estimation of the bulk Lorentz factor, Γ, in the region where gamma rays are produced,[2] providing insight into the internal GRB environment as well as the expected neutrino flux from GRBs, which is sensitive to Γ (see Ref. 3). In addition, the GRB spectrum above 10 GeV, such as that searched for with the High-Altitude Water Cherenkov (HAWC) Observatory's GRB program, can be used to constrain possible Beyond-the-Standard-Model physics that contains Lorentz invariance violations.[4] Alternatively, interpreting a spectral cutoff as attenuation of GRB photons from pair-production on extragalactic background light (EBL) provides constraints on EBL density over cosmological distances.[5]

There are at least two known classes of GRBs: short GRBs have durations of less than two seconds and a peak νF_ν at Earth of ~ 1 MeV,[4] whereas long GRBs

last more than two seconds and the peak of νF_ν at Earth is $\sim$ 150–200 keV.[6] Short GRBs, with their harder spectrum, are believed to be the result of the merger of two compact objects, such as two neutron stars or a neutron star and a solar mass black hole.[7–9] Core-collapse supernova type Ic are believed to be the progenitors of long GRBs, supported by observed coincidences of the two phenomena.[10] However, because the occurrences of either class of GRB cannot be predicted, ground-based observations of such sources are limited by slewing times— especially detrimental for short GRBs.

2. The Highest-Energy Emission from GRBs

For both short and long GRBs, emission is believed to happen in highly relativistic narrow jets that point in the direction of Earth. Prompt GRB emission (that is, emission from the first seconds of the GRB) is detected in the keV–MeV band by space-borne instruments such as the *Fermi*-GBM[11] and Swift-BAT.[12] Satellites with instruments sensitive to hard gamma rays, such as the *Fermi*-LAT and imaging atmospheric Cherenkov telescopes (IACTs) such as the MAGIC telescopes and the HESS array, have shown that GRBs are capable of producing very-high-energy (VHE) photons. Prominent examples include GRB 130427A,[13] observed up to 126 GeV by the *Fermi*-LAT; GRB 180720B,[14] detected using the H.E.S.S. Array at 100 GeV $< E_\gamma <$ 1 TeV; and GRB 190114C,[15,16] observed up to 1 TeV by the MAGIC telescopes approximately one minute after triggering the *Fermi*-GBM and Swift-BAT. However, due to the limited field-of-view of IACTs, it is difficult for observations above the energy threshold for the *Fermi*-LAT to occur in the first few seconds of the GRB. By contrast, the HAWC Observatory observes 1/6th of the sky at once and has near-continuous uptime to search for GRBs, making both short GRBs and long GRBs ideal observational topics. This uninterrupted analysis of air showers would be ideal for capturing a high-energy component of the prompt emission, should one be present.

3. The High-Altitude Water Cherenkov (HAWC) Observatory

The HAWC Observatory, a successor to the Milagro Observatory,[17] is a very-high-energy ground-based air shower array located on the side of the Sierra Negra volcano in Mexico at an altitude of 4,100 m above sea level. It has a wide field-of-view of $\sim$ 2 sr at any one time (observing 2/3rds of the sky each day) and covers an energy range from $\sim$300 GeV to above 100 TeV. HAWC consists of 300 cylindrical water tanks in the main array covering a total area of 22,000 m^2. Each tank in the main array is 7.3 m in diameter and 4.5 m deep and is equipped with four (three 8″- and one 10″-diameter) upward-facing photomultiplier tubes (PMTs) anchored to the bottom of the tank.

HAWC has completed installing and integrating an additional "outrigger" array[18] composed of 345 cylindrical tanks 1.55 m in diameter and 1.65 m deep, each

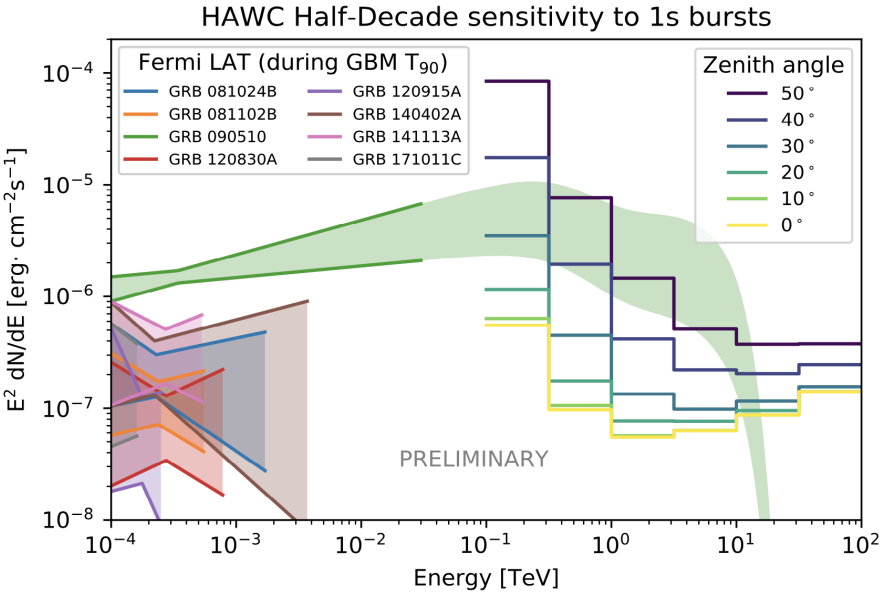
containing a single 8″ PMT. The outriggers are arranged in a concentric, circular, symmetric pattern around the main array, covering an additional instrumented area of ~ 4.5 times that of the main array. The outriggers provide enhanced sensitivity above 10 TeV by allowing the accurate determination of core position for showers off the main tank array and increase the effective area above 10 TeV by a factor of 3–4.

In both the main array and the outriggers, the PMTs detect Cherenkov light from secondary particles created in extensive air showers induced by very-high-energy gamma rays and cosmic rays incident on Earth's atmosphere. The main data acquisition system measures the arrival time of secondary particles at ground level and the amplitude of the PMT signals. This information, processed in near real time (only ~ 4 seconds delay), is used to reconstruct the arrival direction and energy of the primary particle all day, every day. The angular resolution of HAWC ranges from $\sim 0.2^\circ$ (at its highest energies) to 1.0° (at its lowest energies).[19] With these features and a duty cycle greater than 95%, HAWC is ideally suited to continuously monitor the Northern Hemisphere sky for high-energy emission from gamma-ray transients such as GRBs to find new sources as well as search archival data.

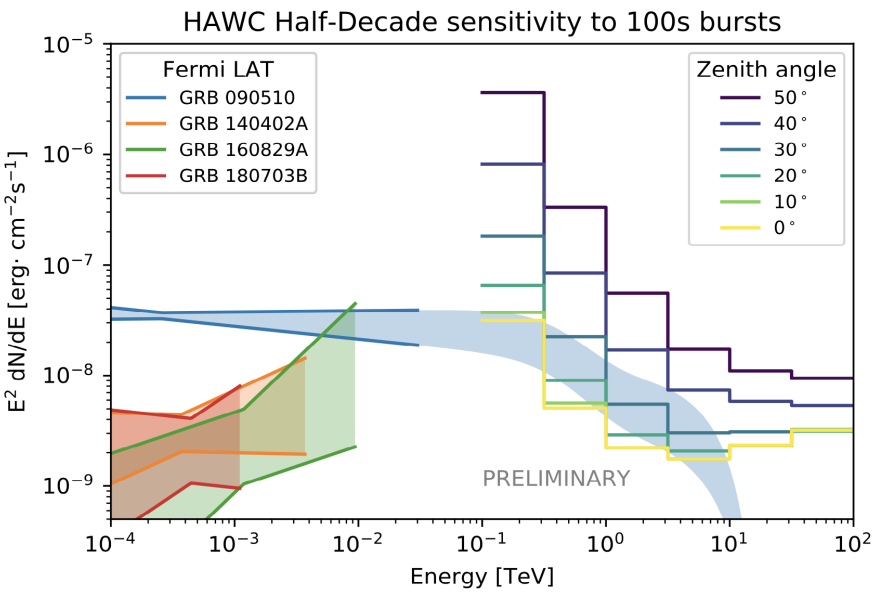
3.1. *The Gamma-Ray Detector Landscape*

HAWC's wide field-of-view and continuous operations are advantageous for detecting burst transients with emission durations shorter than the slewing times of Imaging Atmospheric Cherenkov Telescopes (IACTs), such as the prompt emission from GRBs. IACTs are also additionally limited by the need for small localization errors on triggered sources and their requirements for good weather and nighttime-only observations. While satellites are obviously very effective tools for the observation of both short and long GRBs, their limited size means satellites are not expected to provide useful statistics above tens of TeV— HAWC's effective area is > 100 times the size of *Fermi* at energies > 100 GeV. Additionally, HAWC's ability to observe GRBs before, during, and after the prompt emission phase measured by satellites is essential for determining the start time and duration of prompt emission at ~ 300 GeV— relatively unknown given the paucity of photons detected by satellites at these energies.

While HAWC is more sensitive to long GRBs, it occupies a unique position in terms of observing short GRBs due to the lack of slewing time and high energy range. This detector is therefore poised as a double-threat ad both classes of GRBs should be prime observational and analytical targets for us. The half-decade sensitivity calculations project a higher quasi-differential sensitivity than the *Fermi*-LAT[20] to both short and long bursts in the energy regime of interest herein, as shown in Figure 1.



(a) HAWC quasi-differential sensitivity to 1s bursts



(b) HAWC quasi-differential sensitivity to 100s bursts

Fig. 1. HAWC quasi-differential sensitivity to both short (a) and long (b) bursts as a function of zenith angle, defined as the mean flux in a given half-decade that would result in at least a 5σ detection half of the time. For reference we include spectra measured by the Fermi-LAT detector for short GRBs (on the order of 1s) and long GRBs (duration > 70 s), respectively. Figures by Israel Martinez-Castellanos.

4. The HAWC GRB Program

The HAWC GRB program consists of two dedicated analyses: a self-triggered, all-sky search, and rapid response follow-ups of GRBs reported by satellites. Both methods are performed in real time using the quick-look air shower reconstruction produced at the HAWC site with a latency of ∼five seconds. Additionally, each search is repeated on archival data with improved calibration and reconstruction algorithms.[1] This archival data is especially important for following up on reported emission from IACTs.

From the sensitivity of the HAWC Observatory, ~ 0.5 GRB detections per year are expected from following satellite-reported GRBs alone, assuming most GRBs do not contain an intrinsic cutoff below 200 Gev.[4] The all-sky search method yields similar expectation as the trials penalty taken when searching the full sky is roughly compensated by the ability to search data without satellite coverage.[21] Thus far, there have been no significant detections of GRB transients since the inauguration of the full HAWC detector on March 20, 2015.

4.1. *Self-Triggered, All-Sky Search*

The self-triggered all-sky method continuously searches for transient signals from GRBs above an energy threshold of 300 GeV using sliding time windows. The four time windows used are of lengths 0.2, 1, 10, and 100 seconds, typical of peak structures within GRB light curves. The all-sky search shifts each window forward in time by 10% of its width, binning air shower events during that window using a grid of $2.1^\circ \times 2.1^\circ$ square spatial bins covering all points within 50° of detector zenith,[21] as shown in Figure 2. The number of showers in each spatial bin is then compared to the expectation from well-modeled, charged cosmic-ray backgrounds, producing a p-value. Locations with an air-shower excess corresponding to a post-trials false alarm rate of one event per day are considered candidates for GRB transients and reported internally within HAWC.

This style of analysis is not limited to having to continuously search the entirety of the sky for a transient signal, but also possesses the ability to be passed an external trigger in order to perform a limited sliding time window search near the trigger time and location of known GRBs beyond just that of the satellite follow-ups described below. The analysis chain is the same whether continuous or externally triggered. This allows for the fine-tuning of the start time of very-high-energy emission when performing follow-ups. Though this analysis is performed in real-time, especially for external triggers, performing this analysis on archival data allows inspection *before* the trigger time, an ability unique to wide-field-of-view survey instruments such as HAWC, which are not limited to only looking forward in the way that IACTs are.

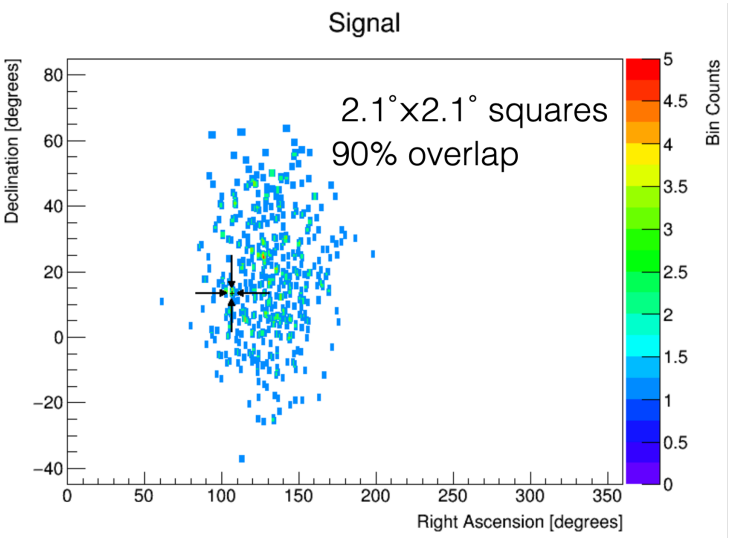


Fig. 2. The 90% overlap in spatial bins created by shifting each window by 10% of its width guarantees that the signal will be ideally oversampled such that there is a bin in which the signal is centered. Figure by Joshua Wood.

4.2. *Rapid Response Follow-Up*

The method for rapid response follow-up of reported GRBs is simpler in that it fixes the search window start time to match the external trigger time provided by a satellite (*e.g.*, the *Fermi*-GBM[11]); follow-ups of GCN Notices for triggered searches occur with $\sim$ 30 minutes latency. Additionally, the spatial portion of the search is restricted to the reported error on the GRB location. The analytical framework is the same as with the all-sky search, with air-shower events during the search window binned into spatial bins and compared against the expectation from well-modeled, charged cosmic-ray backgrounds.[22] Events can be separated based on quality and background, among other improvements. In cases when T_{90} is available with the external trigger, we search for emission occurring within T_{90} as well as $3 \times T_{90}$ and $10 \times T_{90}$ for long GRBs, and 6 and 20 seconds for short GRBs— the longer windows covering possible extended emission. Otherwise, the follow-up is performed with timescales of 1 and 20 seconds to cover typical T_{90} values as well as a 300-second window to look for extended emission. These timescales grant the ability to test for delayed-onset very-high-energy emission when performing follow-ups of these satellite-detected GRBs. The combined power of observations (or non-observations) from both satellites and ground-based observatories such as HAWC is critical for unlocking the secrets of GRBs, as shown through the agreement of the HAWC limits for both short and long GRBs with GBM observations in Figure 3.

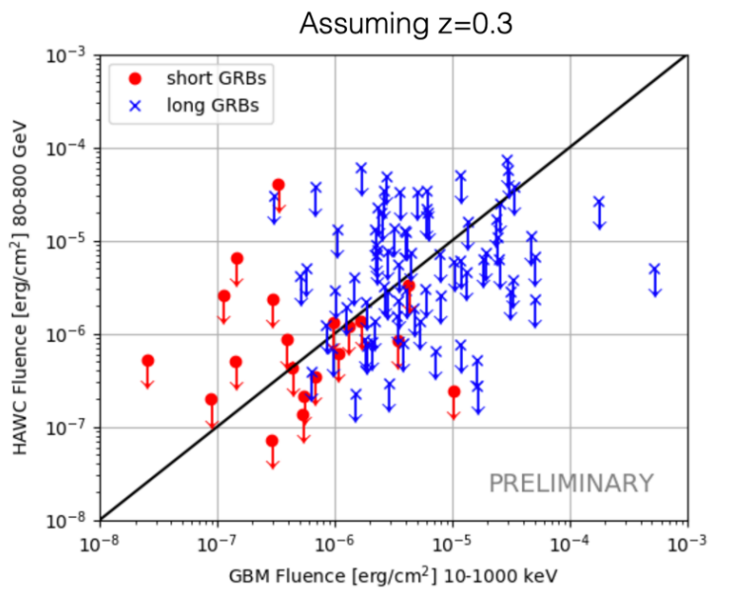

Fig. 3. Even for a non-detection, upper limits for nearby GRBs with known redshift, in combination with information from the triggering satellite(s), can place strong constraints on models.

4.3. *HAWC and the GRB Community*

Despite how ideal the HAWC Observatory is for the observation of very-high-energy emission from GRBs, a significant observation has not yet occurred. Those GRBs that have been detected to-date with a very-high-energy component—GRB 190114C,[15,16] GRB 180720B,[14] and GRB 190829A[23]—were not in the HAWC field of view. However, as shown in Figure 4, HAWC would likely have detected GRB 190114C if it had happened in its field of view.

If HAWC were to trigger on a GRB, structures are in place to alert the community and coordinate alerts between different experiments. The most prompt notification would be the use of GCNs and ATels for confirmed significant observations. HAWC has sent out 47 such circulars in the last year. Additionally, though somewhat delayed, HAWC is already using the Astrophysical Multimessenger Observatory Network (AMON)[24] for sub-threshold triggers. AMON reports "hotspot" parameters for events above the estimated cosmic-ray background level, $> 2.75\sigma$. AMON sends alerts to the GCN if an even passes the false-alarm-rate threshold of one per year, calculated using two years of scrambled datasets from both HAWC and IceCube.

5. Future Outlook

While HAWC has yet to observe a significant signal from a GRB, either self-triggered or as a follow-up, the HAWC Collaboration is very optimistic that recent

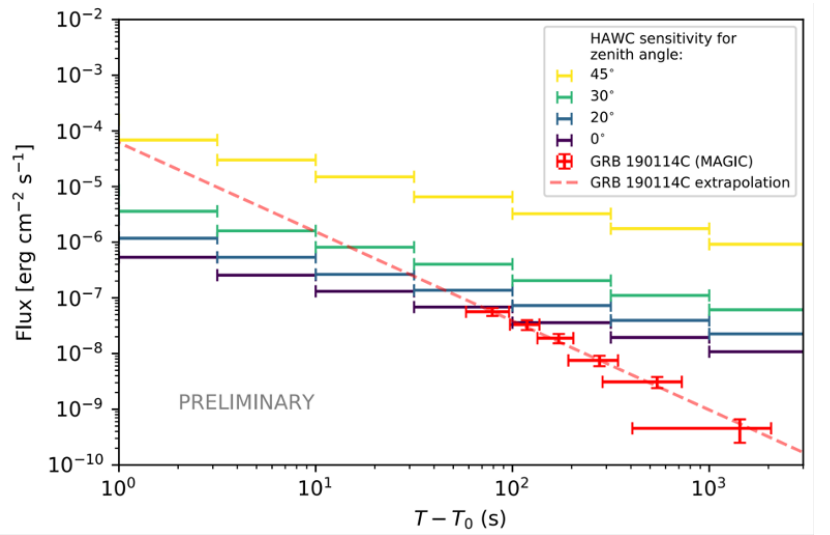

Fig. 4. HAWC's sensitivity at different zenith angles overlaid on an extrapolation of the flux detected by MAGIC from GRB 190114C. Adapted from Ref. 15.

improvements will greatly improve sensitivity to GRBs. This includes better reconstruction for low-energy events (noise reduction), increased statistics from multi-shower fits, and improved angular resolution for multiple showers on the array. Especially critical to the detection of very-high-energy emission from GRBs will be multi-bin, maximum likelihood analyses for short timescales and data reconstructed around known GRBs. The full dataset with these improvements will be ready in the coming months, with planned analyses to utilize these upgrades including both a targeted revisiting of known GRBs in reconstructed archival data, as well as updates to the self-triggered, "blind" search. With such advances at HAWC's fingertips, the HAWC Collaboration is eager for HAWC to broaden the GRB horizons and unlock their secrets through its unique position as a ground-based, wide-field-of-view observatory.

for the CALET Collaboration*

The CALorimetric Electron Telescope (CALET) cosmic ray detector on the International Space Station (ISS) has been in operation since its launch in 2015. The main instrument, the CALET calorimeter, is monitoring the gamma ray sky from 1 GeV up to 10 TeV with a field-of-view of about 2 sr for more than five years. In this paper, we describe the analysis of gamma ray candidate events observed by the calorimeter and report on a search for gamma-ray emission from gravitational-wave event candidates announced by the LIGO/Virgo third observation run from 2019 April to 2020 March.

Keywords: Gamma rays: general – gravitational waves – methods: observational

1. Introduction

The CALorimetric Electron Telescope (CALET),[1] which was successfully launched and installed on the Japanese Experiment Module (JEM) 'Kibo'-Exposed Facility of the International Space Station (ISS) in August 2015, is a mission of the Japanese Aerospace Exploration Agency (JAXA) in collaboration with the Italian Space Agency (ASI) and NASA. The instrument has been taking science data continuously with no major interruptions since 2015 October. The main target of the CALET calorimeter is observation of high-energy cosmic rays,[2] especially electrons,[3] in the energy range from ~ 1 GeV to tens of TeV, and nuclei,[4] from ~ 10 GeV/n to ~ 100 TeV/n, but its fine detector structure allows us to observe high-energy gamma-rays[5] from ~ 1 GeV to ~ 10 TeV.

In this paper, we describe the analysis of gamma-ray candidate events observed by the CALET calorimeter and report on a search for gamma-ray emission from gravitational-wave event candidates announced by the LIGO/Virgo third observing run in the period April 2019 – March 2020. (See Ref. 6 for results during the first and second runs.) Search for low-energy emission using the CALET Gamma-ray Burst Monitor (CGBM) is reported elsewhere.[7]

2. The CALET detector

The CALET payload (Fig. 1) includes scientific and auxiliary equipment for a total mass of 613 kg, dimensions of $1.9 \times 0.8 \times 1.0$ m^3, nominal power consumption

*See the last page for the full authors list.

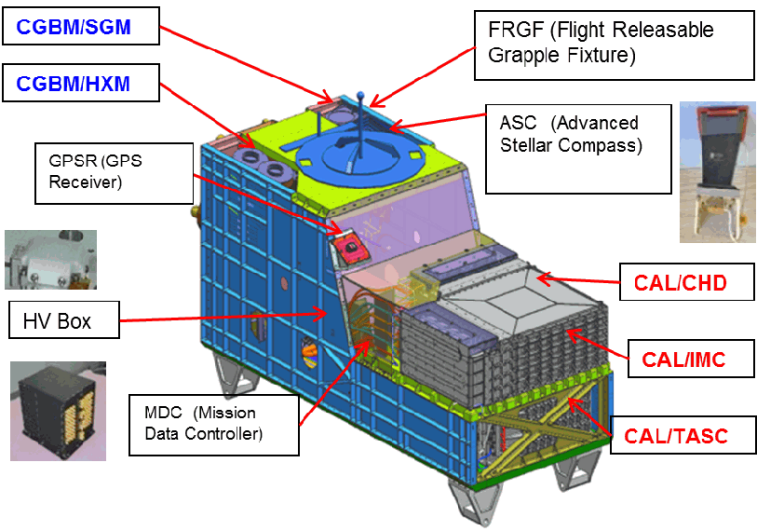

Fig. 1. The CALET payload installed at port No. 9 of the 'Kibo'-Exposed Facility of Japanese Experiment module on the ISS. The CALET calorimeter (CAL) consists of Charge Detector (CHD), Imaging Calorimeter (IMC) and Total Absorption Calorimeter (TASC). The CALET Gamma-ray Burst Monitor (CGBM) consists of two hard X-ray monitor (HXM) units and one soft gamma-ray monitor (SGM) unit.

of 507 W. The main scientific instruments are the electromagnetic calorimeter[1] and the gamma-ray burst monitor (CGBM).[8]

The CALET calorimeter is an all-calorimetric instrument designed to achieve a large proton rejection capability ($>10^5$) with a fine-grained imaging calorimeter (IMC) followed by a total absorption calorimeter (TASC). The overall thickness of CALET at normal incidence is 30 X_0 (radiation length) and ~ 1.3 proton interaction length. The charge identification of individual nuclear species is performed by a two-layered hodoscope of plastic scintillators (CHD) at the top of the apparatus, providing a measurement of the charge Z of the incident particle over a wide dynamic range ($Z = 1$ to ~ 40) with sufficient charge resolution to resolve individual elements ($\Delta Z \sim 0.1$ for light nuclei up to B, 0.3 in the Fe region) and complemented by a redundant charge determination via multiple dE/dx measurements in the IMC.

The IMC is a sampling calorimeter longitudinally segmented into 16 layers of scintillating fibers (SciFi, with 1 mm^2 squared cross-section) interspaced with thin tungsten absorbers. Alternate planes of fibers are arranged along orthogonal directions. Its surface area is 45×45 cm^2 and it can image the early shower profile in the first $3X_0$ and reconstruct the incident direction of cosmic rays with good angular resolution.

The TASC is a $27X_0$ thick homogeneous calorimeter with 12 alternate X-Y layers made of 192 lead-tungstate (PWO) logs. It measures the total energy of the incident

particle and discriminates electrons from hadrons with the help of the information from the CHD and IMC. Each log in the top layer is read by a PMT for use in the trigger system, together with CHD and IMC signals. A dual photodiode / avalanche photodiode system (APD/PD, Hamamatsu Photonics S8664-1010/S1227-33BR) is used for the read-out of the other layers. Such a readout system provides a dynamic range covering 6 orders of magnitudes and enables to measure large energy deposit expected from a proton-induced 1000 TeV shower. The TASC measures the energy of the incident particle with excellent resolution: 2% (3%) for electrons (gamma-rays) with energy $E > 10$ GeV, better than 35% for nuclei up to $\sim$ 100 TeV energy.

Charged particles and gamma rays with energy larger than 10 GeV will be triggered above a 15 MIP (minimum ionizing particle) threshold from the sum of the signals from the last two IMC SciFi belts and a 55 MIP threshold from the signal of the top layer in the TASC ("High-energy shower trigger", HE). Electrons and gamma rays in the energy range between 1 GeV and 10 GeV will be observed only for a limited exposure by reducing the IMC trigger threshold ("Low-energy shower trigger", LE, and "Low-energy gamma-ray trigger, LE-γ, respectively).

The data are transferred via two telemetry channels: one is the Ethernet channel which is operated at a medium rate of 600 kbps, and the other is a MIL-STD-1553B channel which provides low rate data at 50 kbps. In the medium rate mode, an event observed by CALET on the ISS will be transferred to the Tsukuba Space Center (TKSC) of JAXA. The low rate mode is used as a redundant channel for telemetering the CALET house keeping data plus a sample of the cosmic-ray events. The CALET data will be transmitted to TKSC via MSFC in the United State, and are sent to the Waseda CALET Operations Center (WCOC) in real time for monitoring data quality and checking for transient events.[9] The off-line data analysis is performed by the international CALET team based on the data delivered from the WCOC.

3. Analysis for gamma rays

We use two trigger modes of CAL for gamma-ray analysis: a low-energy gamma-ray (LE-γ) mode with an energy threshold $\sim$ 1 GeV used at low geomagnetic latitudes and following a CGBM burst trigger, and a high-energy (HE) mode with a threshold $\sim$ 10 GeV used in normal operation for all particles irrespective of geomagnetic latitude.[9]

The selection process of gamma-ray events used for the HE mode is essentially the same as that described in Ref. 10. For the LE-γ mode the selection and analysis are fully described in Refs. 5, 11. Here we briefly summarize the procedures.[6]

Offline trigger – In order to mitigate the inherent variability of hardware condition of flight data sample, energy deposit thresholds higher than those nominally applied by the hardware trigger are imposed both for LE-γ and HE modes.

Tracking – Event tracks are reconstructed for the HE mode using the EM track algorithm[12] developed for the electron analysis which is a powerful method for reconstructing electromagnetic showers. For the LE-γ mode we use the CC track algorithm[5] optimized for photons with energies below 10 GeV. It begins by finding clusters of hit fibers in the three bottom layers of IMC separately for the X- and Y-projections and extending the candidate tracks to upper layers of IMC. The trajectory with the highest total energy deposit is selected. The subsequent analysis applies only to contained events passing through CHD and having track lengths in TASC more than 26.4 cm for the HE mode, and well contained events whose tracks satisfy more sophisticated geometrical conditions for the LE-γ mode.[5]

Shower shape/hadronic rejection – Low energy gamma-ray events can be mimicked by albedo (i.e. upward moving) secondary charged pions from hadronic interactions in the calorimeter or the support structure. These events are vetoed by requiring to deposit more energy in the bottom layer of IMC than in the layer of pair conversion. Further rejection of events with showers not consistent with a pure electromagnetic cascade is provided by a cut on the IMC concentration, which use the lateral spread of the energy deposit distribution in the lower layers of IMC.

In order to reject hadronic events we utilize the K parameter defined as

$$K = \log_{10} F_E + R_E/2\,\mathrm{cm}$$

where F_E is the fractional energy deposit in the bottom TASC layer with respect to the total energy deposit sum in the TASC and R_E is the second moment of the lateral energy deposit distribution in the top layer of TASC. This method is developed for the derivation of the electron flux and is designed to exploit the larger spread and slower development of proton showers due to penetrating secondary pions.[13]

Charge zero – In order to select events consistent with zero primary charge, cuts are made on the energy deposits in CHD and upper IMC layers. These requirements are designed to veto charged particle events effectively. We require one of three filters utilizing CHD and upper IMC layers (see Ref. 5 for detail).

Since CALET is attached to the exposed facility of the JEM on the ISS, gamma-ray observation with CALET/CAL suffers from secondary gamma rays produced in interactions of high-energy cosmic rays with various structures of the ISS surrounding the detector. Some structures, such as the ISS truss and the JEM, are fixed to the ISS, and we can easily cut those secondary gamma rays by limiting our field-of-view (see Fig. 2 (*Left*)). However, moving structures, such as solar panels and robotic arms, produce time-varying backgrounds for gamma ray observation. In our preceding analysis, we simply rejected events coming from the field-of-view affected by moving structures.[5] We have developed moving filter algorithms to reject time-varying portions of our field-of-view by taking account of moving structures, whose operational data are supplied by JAXA, operating the 'Kibo' module, in order to maximize our exposure for cosmic gamma rays.[14]

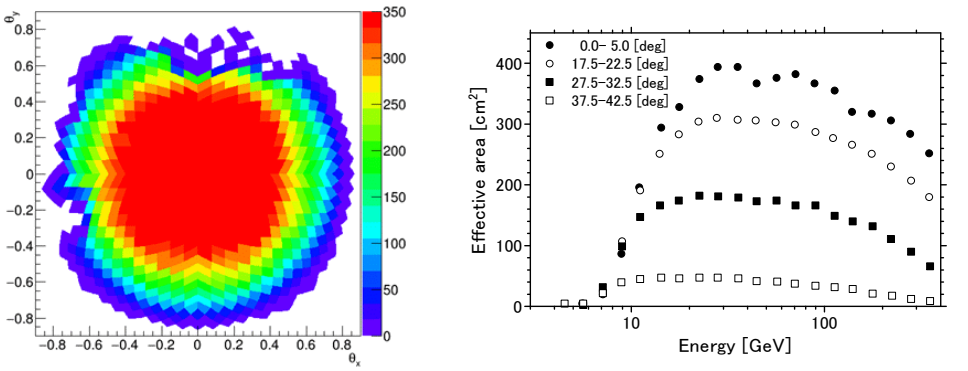

Fig. 2. (*Left*) Field-of-view of CALET/CAL, expressed in effective area (in cm^2) as a function of projected incident angles onto x- and y-plane (θ_x, θ_y). Some inefficient regions seen at edges are caused by cuts to remove secondary gamma rays from ISS structures. (*Right*) Effective area as a function of gamma-ray energy for various incidence-angle ranges.[5]

According to the detailed simulation study, we estimate the effective area and performance. The effective areas for various incident angles are shown in Fig. 2 as a function of energy.[5] The field-of-view is about 2 steradian. The angular resolution[5] and energy resolution[15] are shown in Fig. 3.

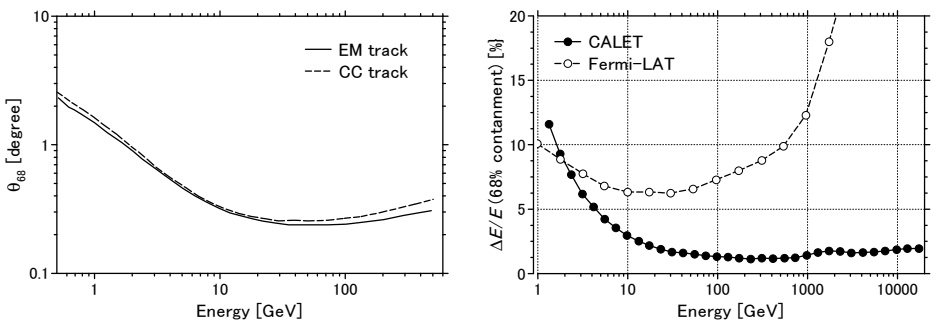

Fig. 3. (*Left*) Angular resolution of CALET for gamma rays as a function of energy, averaged over various shower starting points in IMC.[5] θ_{68} is the half angle of the cone in which 68% of gamma rays are contained. 'EM Track' is an algorithm developed for electron analysis and optimized for HE triggers, and 'CC Track' is another one developed specifically for low-energy (1–10 GeV) gamma-rays. (*Right*) Energy resolution of CALET as a function of energy,[15] compared with that of Fermi-LAT (P8R3SOURCE_V2, Total).[16]

Figure 4 shows a skymap of gamma-ray candidates (LE-γ trigger) for the data during the period 2015 November – 2018 May shown in the Galactic coordinates. Some individual sources are evident. White contours show relative exposures which are not uniform due to the inclined (51.6°) orbit of ISS.

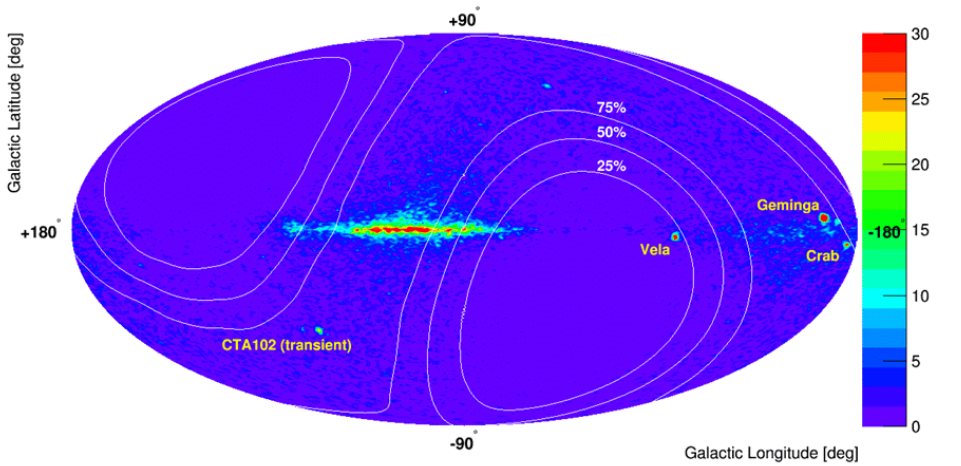

Fig. 4. Skymap of gamma-ray candidates (LE-γ trigger) shown in the Galactic coordinates for the data during the period 2015 November – 2018 May. White contours show relative exposures. Some individual sources are marked.

4. Limits on electromagnetic emission from gravitational events

We have already reported the results on the search for gamma ray emission from gravitational-wave events detected during the first and second observation run of LIGO/Virgo.[6] Also the intermediate result during the third run has been reported.[14] Here we extend the analysis for the whole third run.

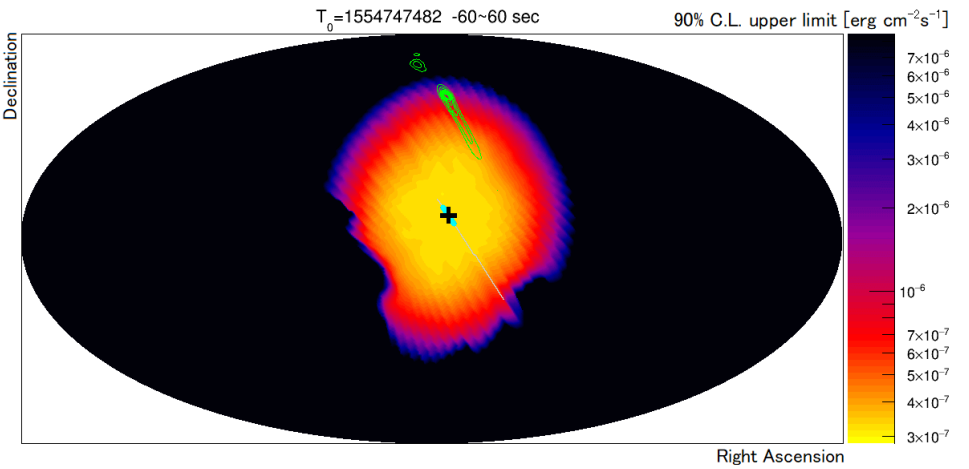

Fig. 5. 90% C.L. upper limit on S190408an energy flux in the energy region 1–10 GeV and time window $[T_0 - 60\text{s}, T_0 + 60\text{ s}]$ shown in the equatorial coordinates. The thick cyan line shows the locus of the FOV center of CAL, and the plus symbol is that at T_0. Also shown by green contours is the localization significance map of S190408an reported by LIGO/Virgo.

Since the beginning of the third run of LIGO/Virgo, we are monitoring possible gamma-ray emission based on the triggers on gravitational-event candidates supplied by the LIGO/Virgo team, in compliance with the memorandum of understanding between CALET and LIGO and Virgo. In Table 1 we summarize the CALET/CAL observations reported in GCN circulars[17] for the third run of LIGO/Virgo, from 2019 April 1 to 2020 March 27. No gamma-ray candidates have been observed in association with these triggers. Upper limits (U.L.) on the gamma-ray energy fluxes are given in unit of erg $\mathrm{cm}^{-2}\mathrm{s}^{-1}$ for the energy range 10–100 GeV except for those marked with † which are for 1–10 GeV, which corresponds to the HE and the LE-γ mode of the trigger condition of CAL around T_0. 'Coverage' is the fraction of the overlapping region of the LIGO/Virgo localization map covered by the CAL field-of-view at T_0 ('No' means there is no overlap). Also shown are the celestial coordinates of the center of CAL field-of-view at T_0. Event type in 'Comments' comes from GraceDB.[18]

An example of the energy flux limit skymaps is shown in Fig. 5 for the LIGO/Virgo trigger S190408an.[14] In this case 80% of the localization significance map of LIGO/Virgo was covered within ± 60 seconds the trigger time (T_0), but there was no gamma-ray candidate. We obtained an upper limit on gamma-ray flux of 2.3×10^{-6} $\mathrm{cm}^{-2}\mathrm{s}^{-1}$ (90% C.L.) in the energy range 1–10 GeV since the CALET was in the LE-γ mode at that time..

Figure 6 shows the monthly variation of the number of LVC alerts and CALET GCN circulars. About 70% of alerts were followed and reported by CALET. Considering that the field-of-view of CAL extends to $\sim 45°$ from the zenith, the chance to have overlap with the LIGO/Virgo probable region is not small. In summary, CALET/CAL was online for 54 triggers, and for 25 triggers there were some overlapping sky area between the CALET field-of-view and the summed LIGO/Virgo probability maps. (19 in the HE mode, 6 in the LE-γ mode), but there were no gamma-ray events associated with triggers in the time window within ± 60 seconds from the trigger time (T_0) .

Although no gamma-ray event has been found for 25 triggers, upper limits on the gamma-ray flux obtained by CALET set some constraints on electromagnetic emission from gravitational-wave events as discussed in Ref. 6.

5. Summary

The CALET cosmic ray detector onboard the ISS has been monitoring cosmic gamma-rays above 1 GeV since 2015 October. In this paper we reported our procedure of gamma-ray analysis and our search for electromagnetic counterparts of gravitational-wave events upon triggers supplied by LIGO/Virgo interferometers during their third observation period, and gave upper limits on gamma-ray emission. Now, since extended operations of CALET have been approved by JAXA/NASA/ASI in March 2021 through the end of 2024, we continue observation

so that we can cover the coming fourth observation run of LIGO/Virgo/KAGRA planned to start no earlier than August 2022.

Acknowledgments

We gratefully acknowledge JAXA's contributions to the development of CALET and to the operations aboard the JEM-EF on the International Space Station. We also wish to express our sincere gratitude to Agenzia Spaziale Italiana (ASI) and NASA for their support of the CALET project. This work was supported in part by JSPS Grant-in-Aid for Scientific Research (S) Number 26220708 and 19H05608, JSPS Grant-in-Aid for Scientific Research (C) Number 16K05382, and by the MEXT-Supported Program for the Strategic Research Foundation at Private Universities (2011-2015) (No. S1101021) at Waseda University. The CALET effort in Italy is supported by ASI under agreement 2013-018-R.0 and its amendments. The CALET effort in the United States is supported by NASA through Grants No. NNX16AB99G, No. NNX16AC02G, and No. NNH14ZDA001N-APRA-0075.

Low-luminosity gamma-ray bursts (GRBs) have small isotropic equivalent gamma-ray energy and luminosity, compared with normal long GRBs. GRB 190829A is a member of this class. Furthermore, very-high-energy gamma-rays were detected by H.E.S.S. with $\sim 20\sigma$ significance. This event had more unusual features. First, it had much smaller isotropic equivalent gamma-ray energy than typical long gamma-ray bursts and is classified as low-luminosity GRB. Second, early X-ray and optical afterglow emission showed a rising part and simultaneously peaked at about 1400 s. We propose an off-axis jet scenario that explains these observational results. In this model, the relativistic beaming effect is responsible for the apparently small isotropic gamma-ray energy and spectral peak energy. Using a jetted afterglow model, we find that the narrow jet, which has the initial Lorentz factor of 350 and the initial jet opening half-angle of 0.015 rad, viewed off-axis can describe the observed achromatic behavior in the X-ray and optical afterglow. Another wide, baryon-loaded jet is necessary for the later-epoch X-ray and radio emissions. Derived parameters explains the very-high-energy gamma-ray flux at 20,000 s.

Keywords: Gamma-ray bursts: individual: GRB 190829A

1. Introduction

Low-luminosity gamma-ray bursts (GRBs) have small isotropic equivalent gamma-ray energy $E_{\rm iso,\gamma}$ and luminosity $L_{\rm iso,\gamma}$, compared with normal long GRBs. For most of them, supernovae are often associated. Currently, the origin is unknown. Possible scenarios are a shock breakout,[18] a low-power relativistic jet,[26] an off-axis jet,[30] and so on.

GRB 190829A is classified as a low-luminosity GRB.[4] The prompt gamma-ray emission (from $\sim$ 10 keV to MeV band) consists of two temporally separated components.[4] The burst started with less energetic emission (hereafter Episode 1

following Chand et al.[4]) with $E_{\rm iso,\gamma} = 3.2 \times 10^{49}$ erg and a peak energy (that is, the photon energy at which the νF_ν-spectrum takes a maximum) $E_p = 120$ keV. After quiescent time interval lasting about 40 s, the second brighter emission (Episode 2) with $E_{\rm iso,\gamma} = 1.9 \times 10^{50}$ erg and $E_p = 11$ keV, appeared. The observed values of $E_{\rm iso,\gamma}$ and E_p of Episode 2 are consistent with Amati relation,[1,21] while those of Episode 1 are in the region of low-luminosity GRBs. Both Episode 1 and 2 have smaller $E_{\rm iso,\gamma}$ and E_p than typical long GRBs.[14] Indeed, GRB 190829A occurred so nearby with a redshift of $z = 0.0785$ that such weak prompt emissions could be observed.

Well-sampled afterglow light curves of GRB 190829A were obtained in X-ray, optical/infrared (IR),[4] radio bands[20] and very-high-enrgy (VHE) gamma-rays.[12] VHE gamma-ray emission was detected by H.E.S.S. about 2×10^4 s after the burst trigger and its significance is $\sim 20\ \sigma$.[12] It is remarkable that early X-ray and optical/IR afterglow emission showed a rising part and simultaneously peaked at about 1.4×10^3 s. Such an "achromatic" behavior is difficult to be explained in standard afterglow model, in which the synchrotron emission has the maximum when the typical frequency ν_m crosses the observation bands.[23] In contrast, the other VHE events, GRB 190114C and 180720B, showed monotonically decaying X-ray afterglow emission.[8,29] Possible interpretations of the achromatic bump are the X-ray flare with optical counterpart,[4,32,34] the afterglow onset of baryon loaded outflow,[9] e^+e^- dust shell,[17] and the reverse shock emission.[22] Another interesting point is that late time ($t > 10^{4-5}$ s) optical/IR emissions are dominated by supernova component.[13]

In this proceeding, we consider off-axis jet scenario to explain those unusual observed properties of GRB 190829A. If the jet is viewed off-axis ($\theta_v < \theta_j$), the relativistic beaming effects cause the prompt emission to be dimmer and softer than on-axis ($\theta_v \sim 0$) viewing case.[16,27,28,30] The bulk Lorentz factor of the jet is initially so high that the afterglow emission is very dim because of the relativistic effect. As the jet decelerates, the beaming effect becomes weak, resulting in the emergence of a rising part in afterglow light curves. After the peak of the emission, the jet has smaller Lorentz factors so that the light curve only weakly depends on the viewing angle. For more details, see our paper (Sato et al.[25]).

2. Model

Following Huang et al.,[15] the dynamics of the shock is numerically computed (see Sato et al.[25] for details). The jet with isotropic-equivalent kinetic energy $E_{\rm iso,K}$, initial Lorentz factor Γ_0, and initial jet opening half-angle θ_0 decelerates via interactions with ISM and forms a thin shell. In calculating synchrotron radiation, we assume that microphysics parameters ϵ_e and ϵ_B, the energy fractions of internal energy going into radiating electrons and magnetic field, are constant. The electron energy distribution in the emitting thin shell has a power-law form with index p. In the slow cooling regime, the electron spectrum has a break at the electron cooling

Lorentz factor γ_c, where we take into account the SSC cooling in the Thomson limit as well as synchrotron energy losses.[5,24,31] Then, it has a form $N(\gamma_e) \propto {\gamma_e}^{-p}$ when $\gamma_m < \gamma_e < \gamma_c$ and $N(\gamma_e) \propto {\gamma_e}^{-p-1}$ when $\gamma_c < \gamma_e$. The flux density F_ν of the afterglow emission that arrives at the observer time T is obtained by integrating the emissivity over the equal arrival time surface (e.g., Granot, Piran, & Sari[10]). Parameters of the present model are isotropic-equivalent kinetic energy $E_{\rm iso,K}$, initial Lorentz factor Γ_0, initial jet opening half-angle θ_0, ISM density n_0, microphysics parameters ϵ_e and ϵ_B, electron power-law index p, and the viewing angle θ_v.

3. Results

In this section, we show our numerical results of synchrotron afterglow emission in the X-ray (10^{18} Hz), optical (V-band), and radio (1.3 and 15.5 GHz) bands, and compare them with observation data of GRB 190829A. The X-ray data are extracted from the *Swift* team website[a].[6,7] The optical V-band data (before the absorption correction) are obtained from Chand et al.[4] In our numerical calculation, we take the V-band extinction $A_{\rm V} = 1.5$ mag.[4] The radio data are taken from Rhodes et al.[20]

First, a single jet viewed off-axis is considered in order to discuss the observed X-ray and optical bumps around $T \sim 1.4 \times 10^2$ s. We adopt $\theta_v = 0.031$ rad, $\theta_0 = 0.015$ rad, $E_{\rm iso,K} = 4.0 \times 10^{53}$ erg, $\Gamma_0 = 350$, $n_0 = 0.01$ cm^{-3}, $\epsilon_e = 0.2$, $\epsilon_B = 5.0 \times 10^{-5}$ and $p = 2.44$. The initial opening half-angle is small, so that we refer to "narrow jet" in the following. However, the jet is still "fat" in the sense $\theta_0 > \Gamma_0^{-1}$, so that the jet dynamics is able to be discussed as in a standard manner. Our off-axis afterglow model well explains the observational results of early X-ray and optical afterglow from about 8×10^2 to 2×10^4 s. An achromatic behavior in the X-ray and optical bands is evident. The off-axis afterglow starts with a rising part because of the relativistic beaming effect.[11] As the jet decelerates, the observed flux increases. When the jet Lorentz factor becomes $\Gamma \sim (\theta_v - \theta_0)^{-1} = 65$, the afterglow light curve takes a maximum. If the adiabatic evolution ($\Gamma \propto t^{-3/8}$) is assumed, the observer time of the flux maximum is analytically given by

$$T_{pk} \sim (1+z) \left(\frac{3E_{\rm iso,K}}{4\pi n_0 m_p c^5} \right)^{\frac{1}{3}} (\theta_v - \theta_0)^{\frac{8}{3}} \quad . \tag{1}$$

For our model parameters, we get $T_{pk} \sim 2 \times 10^3$ s, which is consistent with our numerical results within a factor of two. Parameter dependence has been throughly investigated in Sato et al.[25]

Next, a two-component jet model is considered, in which another "wide jet" is introduced in addition to the narrow jet. The observed flux is simply the superposition of each jet emission components. For the wide jet, we adopt $\theta_0 = 0.1$ rad,

[a] https://www.swift.ac.uk/xrt_curves/00922968/

$E_{\rm iso,K} = 2.0 \times 10^{53}$ erg, $\Gamma_0 = 20$, $\epsilon_e = 0.4$, $\epsilon_B = 1.0 \times 10^{-5}$, and $p = 2.2$. The values of θ_v and n_0 are common for both jets. We assume that the central axes of the two jets are identical ($\theta = 0$) and that the two jets depart from the central engine ($r = 0$) at the same time. One can find in Fig. 1 that early achromatic peaks in the X-ray and optical bands are explained by the off-axis narrow jet emission (dashed lines in the right panel), and that the late X-ray and radio afterglow is interpreted with the wide jet emission (dotted lines).

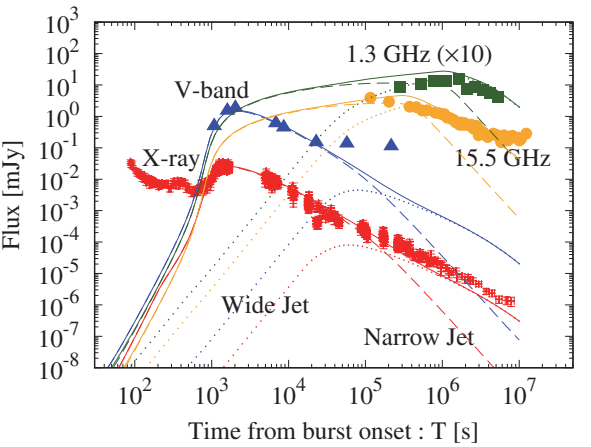

Fig. 1. Afterglow light curves calculated by our two-component jet model — solid lines are the sum of the narrow (dashed lines) and wide (dotted lines) jets in the X-ray (10^{18} Hz: red), optical (V-band: blue) and radio bands (1.3 GHz: orange, 15.5 GHz: green), which is compared with the observed data of GRB 190829A (X-ray: red points, V-band: blue triangles, 1.3 GHz: orange filled-circles, 15.5 GHz: green squares). Note that late-time ($t > 5 \times 10^4$ s) optical band is dominated by supernova component.[13]

4. Discussion

We have investigated an off-axis jet scenario in which we have invoked a two-component jet model to explain the observational results of GRB 190829A. The best-fitted model in this paper is shown by solid lines in Fig. 1. According to our model, the early X-ray and optical afterglow was off-axis emission from the narrow jet, and the late X-ray and radio afterglow came from the wide jet.

There are still some observed components that are brighter than the prediction of our jet model. They may be other components. For example, very early ($T \leq 7 \times 10^2$ s) X-ray emission should be the contribution from late prompt emission like flares. Or if the jet is structured, the early X-ray afterglow shows a plateau phase or an additional peak.[2,3,19] The observed optical flux later than $\sim 5 \times 10^4$ s is a supernova component.[13] At the late epoch ($T \sim 10^7$ s), the 15.5 GHz radio flux also exceeds our numerical result, which could be other components such as counter-jet

emission. As seen in Fig. 1, our theoretical radio fluxes in both 1.3 and 15.5 GHz with our parameters sometimes overshot the observed ones. However, the excess is only within a factor of two, and this difference may come from the uncertainty of our simple model.

The prompt emission of GRB 190829A had smaller values of the peak energy $E_{\rm p}$ and the isotropic-equivalent gamma-ray energy $E_{\rm iso,\gamma}$ than typical long GRBs. Here, it is discussed whether $E_{\rm p}$ and $E_{\rm iso,\gamma}$ from our narrow jet were typical or not if it would have been viewed on-axis ($\theta_v \approx 0$). We consider a simple emission model[16,27,28] assuming an instantaneous emission of an infinitesimally thin shell moving with the Lorentz factor Γ_0. If the narrow jet emitted Episode 1 of observed prompt emission (see § 1), that is, $E_p(\theta_v = 0.031) = 120$ keV and $E_{\rm iso,\gamma}(\theta_v = 0.031) = 3.2\times10^{49}$ erg,[4] then on-axis quantities, $E_p(0)$ and $E_{\rm iso,\gamma}(0)$, are obtained as $E_p(0) = E_p(\theta_v)/R_1 = 3.7$ MeV and $E_{\rm iso,\gamma}(0) = E_{\rm iso,\gamma}(\theta_v)/R_2 = 2.7\times10^{53}$ erg (For details, see Sato et al.[25]). These values are within the range for bursts detected so far (e.g., Zhao et al.[33]). The isotropic equivalent kinetic energy of the narrow jet just after the prompt emission is $E_{\rm iso,K} = 4.0\times10^{53}$ erg (see § 3), so that the efficiency of the prompt emission is calculated as $\eta_\gamma = E_{\rm iso,\gamma}(0)/(E_{\rm iso,\gamma}(0)+E_{\rm iso,K}) \approx 0.4$. On the other hand, if the narrow jet is responsible for Episode 2 (that is, $E_p(\theta_v = 0.031) = 11$ keV and $E_{\rm iso,\gamma}(\theta_v = 0.031) = 1.9\times10^{50}$ erg), we obtain $E_p(0) = 340$ keV and $E_{\rm iso,\gamma}(0) = 1.6\times10^{54}$ erg, which are again similar to typical long GRBs. In this case, the efficiency is $\eta_\gamma \approx 0.8$. If the narrow jet causes Episode 1, then the estimated prompt emission efficiency η_γ is almost typical, however on-axis $E_{\rm p}(0)$ is located at the highest end of the distribution for long GRBs. On the other hand, if the narrow jet produced Episode 2, then on-axis $E_{\rm p}(0)$ is smaller though η_γ is somewhat higher (but it is still comparable, and one can say that the value is reasonable considering very simple approximation of our prompt emission model). Episode 1 and 2 may be emitted from narrow and wide jets, respectively. Note that if the wide jet emits Episode 2, its efficiency is small, $\eta_\gamma \approx 5\times10^{-3}$, so that it might be natural that the narrow jet causes both Episode 1 and 2.

The VHE gamma-ray flux at 2×10^4 s is estimated, where we assume the synchrotron self-Compton emission in the Thomson limit.[24] Our narrow jet parameters determined by X-ray, optical and radio afterglows may roughly explain observed VHE gamma-ray flux at 2×10^4 s.[25] On the other hand, the VHE gamma-ray flux from wide jet has brighten until at 5×10^4 s. After this time, the flux decays.

We propose a backscattering dominated prompt emission model for gamma ray bursts (GRB) prompt phase in which the photons generated through pair annihilation at the centre of the burst are backscattered through Compton scattering by an outflowing stellar cork. We show that the obtained spectra are capable of explaining the low and high energy slopes as well as the distribution of spectral peak energies in their observed prompt spectra.

Keywords: High energy astrophysics; Gamma-ray bursts; Relativistic jets; Theoretical models

1. Introduction

In the picture of gamma ray bursts (GRBs), collapse of a massive star gives rise to a long GRB, while a merger of two compact objects leads to a short GRB. In both the cases, strong bipolar jets are produced.[1,2] Radiation from these jets is observed if the observer is near the jet axis. The initial phase of the burst is known as prompt phase. In a typical understanding of this phase, the jet propagates inside the stellar interior and forms an envelope (stellar cork). Finally, the jet breaks out of the cork to be observed.[3,4]

An alternate view of this stage was proposed,[5–9] in which the core of the star produces electron-positron pair plasma through neutrino annihilation. This pair plasma emits radiation in form of a jet through pair annihilation and pushes the stellar material to form the stellar cork. This cork is further pushed to relativistic speeds by radiation pressure. The radiation is not able to pierce the cork and is backscattered. As the cork is moving with relativistic speeds, this radiation is beamed along the direction of the jet and is seen by the observer.

In this work, we carry out Monte Carlo simulations of the interaction of the seed photons with the cork where the backscattered photons lead to the observed spectrum. We show that the spectrum observed is capable of explaining a large range of observed spectral properties like the photon indices at low and high energies along with the spectral peak energies.

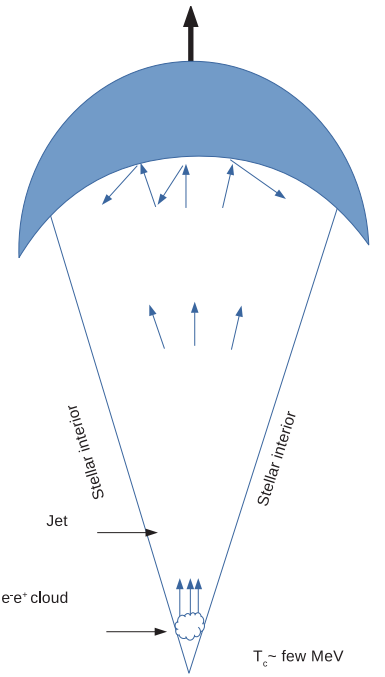

Fig. 1. Geometric representation of the system. The seed photons are generated near the centre of the bursts through pair annihilation and comptonized with the plasma present there. These photons propogate in empty jet funnel and interact with a radially outflowing stellar cork.

2. Physical picture of the system and source of the seed photons

At the time of stellar collapse, neutrinos are produced and get annihilated near the centre of the star. This annihilation produces an electron-positron pair dominated plasma. This pair plasma produces annihilation spectrum along with bremmstrahlung and is further Comptonized by the local plasma. Using Monte Carlo simulations, the resultant spectra were studied by.[10] The spectra were found to be flat with exponential decay at high energies. We obtained numerical fits to his results. For plasma density $n = 2 \times 10^{18}$ cm^{-3} the fitted spectrum is

$$F_\varepsilon = C_0 \exp\left(-\frac{C_1 \varepsilon^2}{\Theta_r^2}\right) \quad \text{KeV/s/KeV}^{-1} \tag{1}$$

Here ε photon energy normalized to electron's rest mass energy. $\Theta_r = k_B T_r / m_e c^2$ is dimensionless representation of pair temperature T_r with k_B, m_e and c are Boltzmann's constant, rest mass of the electron and light speed, respectively. $C_1 = 0.045$ and $C_0 (= 2 \times 10^{40}$ KeV s^{-1}/KeV). This fit gives reliable spectra for temperatures $\Theta_r > 0.3$. The photons with this spectral shape propagate within the jet funnel and push the stellar matter that forms a stellar cork ahead of it. The cork moves with relativistic speeds and escapes the stellar surface. The seed photons enter the

hot cork with temperature T_c (or $\Theta_c = k_B T_c / m_e c^2$). After going through Compton scattering with the electrons inside the cork, the photons gain or loose energy and get backscattered from the rear end. The geometry of this figure is explained in Figure 1. Because of the relativistic motion of the cork with Lorentz factor γ, these photons are then observed by an observer situated at angle θ_{obs} from the jet axis. The cork has curved inner surface and the photons scattered at different locations are observed at different times as well as with different energies producing a light curve as well as spectrum.

3. Solution procedure

Through a Monte Carlo code, we inject approximately 26 million seed photons with the spectral distribution according to Equation 1. These photons are launched at an adiabatically expanding and outflowing cork with temperature T_c and Lorentz factor γ with an opening angle $\theta_j = 0.1$ rad. The photons enter the cork from its rear end (Figure 1) and scattered backwards. Before escaping, the photons go though multiple scattering with energetic electrons inside the cork and thus their energies evolve. More details of the calculation procedure of the Monte Carlo code is described before.[8,11] These photons are then observed in specific angular patch $d\theta_{obs} = 0.005$ rad about the observer's location θ_{obs}. The resultant spectrum is shown in the rest frame of the GRBs with an assumption that the total energy released from the centre is equivalent to 10^{50} erg.

4. Results

In Figure 2, we plot a typical photon spectrum (photons $\mathrm{cm}^{-2}\mathrm{KeV}^{-1}$) obtained by scattering of seed photons with $\Theta_r = 3$ and cork temperature $\Theta_c = 1.4$. The cork has a bulk Lorentz factor $\gamma = 100$ and initial location at $r_i = 3 \times 10^{12}$cm from the centre of the star. The opening angle of the cork is taken to be $\theta_j = 0.1$ rad. The spectrum obtained has a low energy photon index $\alpha = -1.1$ while high energy index is $\beta = -2.75$. In Figure 3 we show the variation of spectral emissivity KeV cm^{-2}. The Spectral peak is obtained to be at $\varepsilon_{peak} = 30$ MeV. This typical spectrum obtained resembles the well known GRB prompt phase spectral shape with two power laws separated by a spectral peak.[12]

Keeping the same parameters as above, we plot the variation of ε_{peak} with observer's position θ_{obs} in Figure 4 and find that it varies from few 10 MeV to few KeV as the observing angle changes from 0 to 0.35 rad. The evolution of peak energies are followed due to relativistic kinematics. The photons are blueshifted for an on axis observer while a far off axis observer sees the photons to be having relatively less energies. This shifts the spectra to lower energies and subsequently low peak energies are observed. The obtained range of peak energies explains the typically observed range of the spectral peaks in GRB prompt phase spectra.[13]

Finally, in Figure 5 we show that the photon indices α and β are sensitive to the cork temperature Θ_c. In the range $\Theta_c = 1 - 10$, the magnitude of both indices

decreases making the spectra harder. It is understandable as the spectrum becomes harder due to high energy electrons in cork at high temperatures.

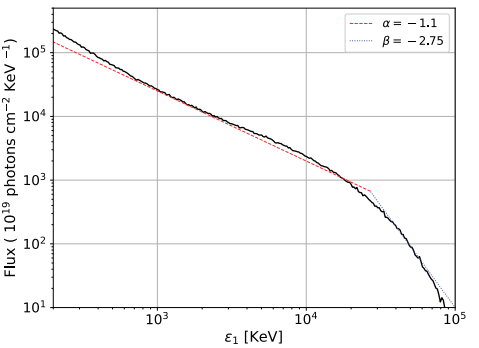

Fig. 2. Photon spectrum obtained for $\Theta_c = 1.4$, and $\theta_j = 0.1$rad. The observer is situated at $\theta_{obs} = 0.05$ rad. Here $\Theta_r = 3.0$ and $\gamma = 100$

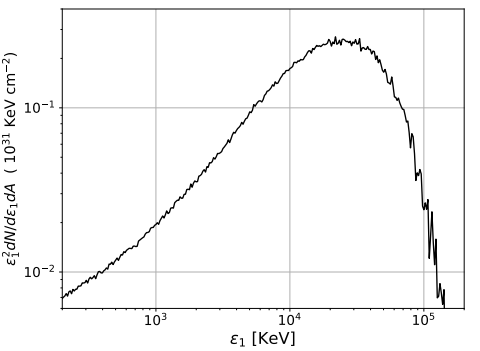

Fig. 3. Emissivity KeV cm^{-2} for the same parameters as in Figure 2

5. Conclusions

In this proceedings, we have shown that the typical spectrum of a gamma ray prompt phase is consistent with the theoretical prediction of backscattering dominated picture. We show that the spectrum has negative α and steeper β. The ranges obtained for both the indices is $\alpha \sim -1.9$ to -1.1 and $\beta \sim -3$ to -2.4. The spectral peak energies decrease as the observer is located farther from the axis or θ_{obs} is greater. In such as case, the peak energies are obtained to be in the range ε_{peak} = few 10 KeV to few 10 MeV. All the obtained ranges of these parameters, α, β and ε_{peak} are within the observed ranges of GRB prompt phase observations.[12–14]

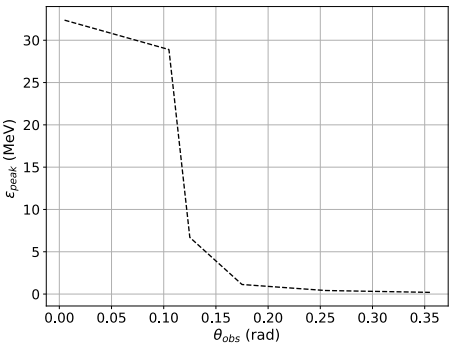

Fig. 4. Variation of the spectral peak energy ε_{peak} with observer's angle θ_{obs} for the parameters as in Figure 2.

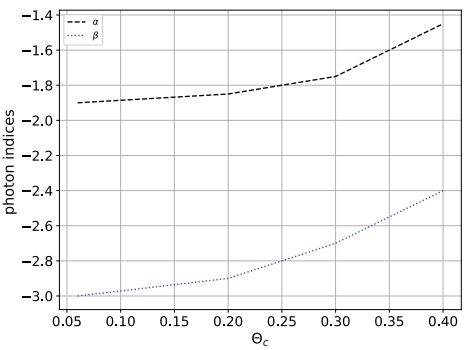

Fig. 5. Variation of photon indices α and β with the cork temperature Θ_c for $\Theta_r = 3$ and $\theta_{obs} = 0.105$ rad.

Applying models of pulsar wind nebulae to explain X-ray plateaux following short Gamma-Ray Bursts

L. C. Strang* and A. Melatos

School of Physics, University of Melbourne, Parkville, VIC 3010, Australia
** E-mail: lstrang@student.unimelb.edu.au*

Many short Gamma-Ray Bursts (sGRBs) have a prolonged plateau in the X-ray afterglow lasting up to tens of thousands of seconds. A central engine injecting energy into the remnant may fuel the plateau. A simple analytic model describing the interaction of the magnetized relativistic wind from a rapidly-rotating magnetar with the surrounding environment can reproduce X-ray plateaux and instantaneous spectra. The model is analogous to classic, well-established models of young supernova remnants and applies the underlying physics to sGRB remnants. The light curve and spectra produced by the model are compared to observations of GRB 130603B. The spectra are also used to estimate parameters of the magnetar including its poloidal field strength and angular frequency. If combined with a gravitational wave signal, this model could provide insight into multimessenger astronomy and neutron star physics.

Keywords: Gamma-ray bursts; afterglow; supernova remnants

1. Introduction

Many short gamma-ray bursts (sGRBs) display long-lived emission in the X-ray band. A subset of the X-ray afterglows are "canonical" afterglows with three components: an initial decay, a flat plateau lasting from 10 s – 10^5 s, and a final decay (typically $\sim t^{-2}$).[1,2] The luminosity and duration of the plateau are correlated, with brighter plateaux ending sooner.[3] A similar phenomenon is observed in long gamma-ray bursts (LGRBs), but the two populations are statistically distinct and likely have different progenitors for the afterglow as well as the prompt emission.[4–6]

Binary neutron star coalescence has been confirmed as a progenitor of sGRBs,[7,8] suggesting the evolution of the post-merger remnant dictates the evolution of the afterglow. X-ray plateaux have inspired several models including fireballs (with[9,10] and without[11] energy injection), fall-back accretion onto a black hole,[12] and ongoing energy injection via a central engine,[13] commonly assumed to be a millisecond magnetar.[14] In the latter scenario, the rotational energy of the magnetar is converted to X-rays via an unknown dissipative process, perhaps involving a relativistic wind.[13–19] Previous models have considered the evolution of a magnetar surrounded

by a shroud of optically-thick ejecta material[20–22] or the production of X-rays via radiative losses from interactions with the surrounding environment.[23,24]

In this work, we present results from Ref. 25 and Ref. 26 exploring a millisecond magnetar central engine through the lens of classic models of pulsar wind nebulae (PWNe), also known as plerions. The term plerion is used throughout Ref. 25 and Ref. 26. Here, we use the term PWNe throughout to emphasize the analogy to supernova remnant models such as Ref. 27 (although technically, we are discussing a magnetar wind nebula and not a pulsar wind nebula). In the PWNe model, the X-ray plateau is caused by a magnetized bubble of electrons fuelled by the relativistic wind of the magnetar. We summarize the model presented in Ref. 25 in Sec. 2 and explore associated synchrotron light curves in Sec. 3. In Sec. 4, we quote results from Ref. 26 inferring parameters of the central engine using instantaneous spectra. We conclude in Sec. 5. This paper borrows substantially from the form and content of Ref. 25 and Ref. 26; among other things, it includes Fig. 3 from Ref. 26 unchanged.

2. Pulsar Wind Model

If a neutron star survives the sGRB, it evolves under the same physics that dictates the early evolution of PWNe. Classic one-zone models for PWNe provide an analytic estimate of the synchrotron luminosity of the remnant without specifying its detailed geometry.[27,28] In Ref. 25, an analogous model is developed and applied to X-ray plateaux. In this scenario, the sGRB heralds the birth of a rapidly-rotating neutron star with a dipole, magnetar-strength external magnetic field with angular frequency $\Omega(t)$, initial angular frequency Ω_0, and polar surface magnetic field strength B_0. Simultaneously, an isotropic, relativistic blast wave (described by the Blandford-McKee self-similar solution[29]) detonates and sweeps up the surrounding interstellar medium into a spherical shell expanding at $v_{\rm s}$.

The neutron star spins down under pure magnetic-dipole braking and radiates energy at a rate

$$L_{\rm sd}(t) = L_0 \left(1 + \frac{t}{\tau}\right)^{-2} \tag{1}$$

where $L_0 \propto B_0^2 \Omega_0^4$ is the initial spin-down luminosity and $\tau \propto B_0^{-2} \Omega_0^{-2}$ is the characteristic spin-down timescale. Through analogy with classic models of PWNe, we assume the energy is extracted as a magnetized, relativistic electron-positron wind with velocity $v_{\rm w} \gg v_{\rm s}$. The ratio of the Poynting flux to kinetic-energy flux in the wind, σ, is expected to be $\gtrsim 1$ (i.e. the wind is Poynting-flux dominated) near the star and $\ll 1$ (i.e. kinetic-energy flux dominated) at distances far beyond the co-rotation radius $c/\Omega(t)$ ($\sigma \approx 10^{-3}$ for the Crab[30–32]).

As in PWNe, a reverse shock forms at radius $r_{\rm rs}$ where the ram pressure of the wind $P_{\rm ram}(r)$ balances the external static pressure $P_{\rm stat}(r)$.[28] As the shock propagates into the wind, the electrons are shocked into a power-law energy distribution $\propto E^{-a}$. Reference 25 models the electron population with a spherical, homogeneous

bubble characterized by its properties at $r_{\rm rs}$ (i.e. at $r = \dot{r}_{\rm rs}t$ for constant $\dot{r}_{\rm rs}$). Under this assumption, the fresh electrons in the energy range $[E_{-0}, E_{+0}]$ are injected into the bubble at a rate

$$\dot{N}_{\rm inj} = \frac{L_{\rm sd}(t)E^{-a}(a-2)}{(1+\sigma)\left(E_{-0}^{2-a} - E_{+0}^{2-a}\right)}. \tag{2}$$

The bubble expands at a rate $\dot{r}_{\rm rs}$, so electrons cool according to adiabatic expansion at a rate

$$-\left.\frac{{\rm d}E}{{\rm d}t}\right|_{\rm adiabatic} = \frac{E}{t}. \tag{3}$$

Given a magnetic field in the bubble $B(t)$, the electrons also cool via synchrotron radiation at a rate

$$-\left.\frac{{\rm d}E}{{\rm d}t}\right|_{\rm synch} = c_s E^2 B(t)^2 \tag{4}$$

where $c_s = \mu_0 e^4/9\pi c^3 m_e^4$. Two magnetic field configurations are presented in Ref. 25. In the first case, henceforth model A, $B(t)$ is taken to be the far-field extension of the stellar dipole field at radial distance $\dot{r}_{\rm rs}t$ (see Eq. (9) in Ref. 25). In the second case, henceforth model B, $B(t)$ is taken to be an arbitrary, constant B. Model B serves two purposes. One, it allows the PWNe model (including magnetar spin down, electron injection, and cooling mechanisms) to be assessed in general terms, even if the specific magnetic field structure in model A is a poor approximation to reality. Two, model B decouples $B(t)$ and the central engine parameters B_0 and Ω_0 (which also govern $\dot{N}_{\rm inj}$), allowing for the possibility that $B(t)$ may be affected by components of the post-merger environment other than the central engine.

The number density of electrons per unit energy $N(E,t)$ can be found via the time-dependent, inhomogeneous partial-differential equation

$$\frac{\partial N(E,t)}{\partial t} = \frac{\partial}{\partial E}\left[\left.\frac{{\rm d}E}{{\rm d}t}\right|_{\rm adiabatic} + \left.\frac{{\rm d}E}{{\rm d}t}\right|_{\rm synch}\right] + \dot{N}_{\rm inj} \tag{5}$$

where adiabatic cooling is defined as in Eq. (3), synchrotron cooling is defined in Eq. (4), and electron injection $\dot{N}_{\rm inj}$ is defined in Eq. (2). Two analytic Green's function solutions (corresponding to models A and B) are found in Ref. 25 and integrated to obtain $N(E,t)$.

3. Light Curves

In this section, we highlight results from Ref. 25 comparing the X-ray synchrotron light curves predicted by the model in Sec. 2 to those observed by the Neil Gehrels *Swift* telescope.[33–35]

The synchrotron spectrum of an electron with energy $E_{\rm c}$ may be approximated as a Dirac-delta function centred at the characteristic synchrotron frequency

$\nu_c \propto E_c^2 B(t)$. The source frame synchrotron luminosity in the range $[\nu_{\rm min}, \nu_{\rm max}]$ is

$$L_{\nu_{\rm min}-\nu_{\rm max}} = \int_{\nu_{\rm min}}^{\nu_{\rm max}} {\rm d}\nu c_s B(t)^2 E_c^2 N(E_c, t). \quad (6)$$

We define $L_{\rm X}$ as the source-frame luminosity in the band corresponding to the 0.3 keV – 10 keV band in the lab frame, i.e. the luminosity observable by *Swift*.

We use GRB 130603B as a representative example of X-ray plateaux following sGRBs because it has a known redshift[36] and has been inferred to spin down under magnetic-dipole braking.[19] We display the observed light curve in Fig. 1 and overplot with a projected light curve from the PWNe model. Black crosses are observations of GRB 130603B by *Swift* and corrected to the source frame. The blue curve is the X-ray light curve predicted by the PWNe model with $B = 10\,{\rm G}$, $B_0 = 4 \times 10^{15}\,{\rm G}$, $\Omega_0/2\pi = 140\,{\rm Hz}$, and $a = 2.8$. The parameters are chosen by hand, guided by results from Ref. 26. The observed and predicted light curve are in broad agreement.

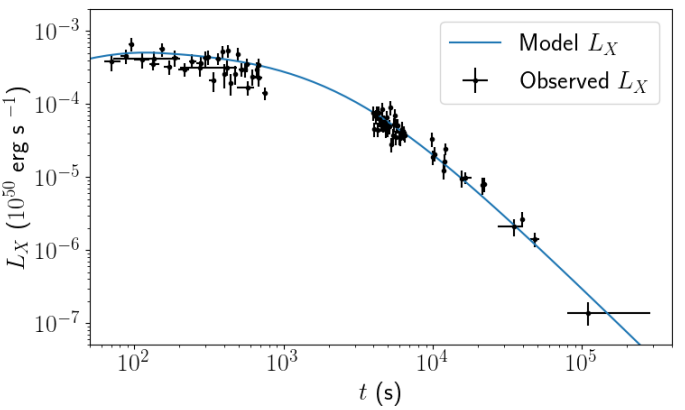

Fig. 1. X-ray luminosity in the source frame $L_{\rm X}\,(10^{50}{\rm erg\,s^{-1}})$ versus time $t\,({\rm s})$. Here "X-ray" refers to the 0.3 keV – 10 keV band observable by *Swift* corrected to the source frame. Black crosses are observations of GRB 130603B by *Swift* and corrected to the source frame. The blue curve is the X-ray light curve predicted by the PWNe model with $B = 10\,{\rm G}$, $B_0 = 4 \times 10^{15}\,{\rm G}$, $\Omega_0/2\pi = 140\,{\rm Hz}$, and $a = 2.8$. Parameters chosen by hand, guided by results from Ref. 26.

In some cases, such as GRB 090515, the plateau ends abruptly. In the context of the central engine model, this has been interpreted as the neutron star collapsing to a black hole and terminating energy injection[18] (we note, however, recent population-based arguments against this hypothesis[37]). In the PWNe model, the collapse of the neutron star halts injection only but does not remove the existing population of electrons, so the afterglow persists for some time, given approximately by the synchrotron lifetime $t_{\rm synch} \sim 2 \times 10^{-9}\,[B/(1\,{\rm G})]^{-3/2}\,[\nu_c/(1\,{\rm keV})]^{-1/2}$ s. In the X-ray band, and for the parameters in Figure 1, $t_{\rm synch}$ amounts to nanoseconds.

3.1. *Luminosity-time correlation*

The Dainotti correlation connects the plateau luminosity $L_{\rm p}$ and plateau duration $t_{\rm p}$ in GRB plateaux which states that brighter plateaux have shorter durations than dimmer plateaux.[3,38,39] This correlation has been studied extensively for LGRBs under a variety of assumptions[40,41] (see Ref. 42 for a thorough review on the correlation and its uses).

The PWNe model presented in Ref. 25 naturally reproduces the observed correlation for reasonable definitions of $L_{\rm p}$ and $t_{\rm p}$. One reasonable choice is to define the X-ray plateau duration as $t_{\rm p} = \tau$ and the corresponding luminosity as $L_{\rm p} = L_{\rm X}(t = \tau)$. The light blue region in Fig. 2 indicates the full range of ($L_{\rm p}$, $t_{\rm p}$) pairs generated by the PWNe model for $B = 5.0 \times 10^{-1}\,{\rm G}$, $E_{-0} = 2.5 \times 10^{-2}\,{\rm erg}$, $10^{12} \leq B_0/(1\,{\rm G}) \leq 10^{16}$, and $\Omega_0/2\pi \leq 10^3\,{\rm Hz}$. The black line and grey-shaded region corresponds to the best-fit correlation from Ref. 18 based on a sample of 159 sGRBs and LGRBs. The observed correlation falls entirely within the range permitted by the PWNe model.

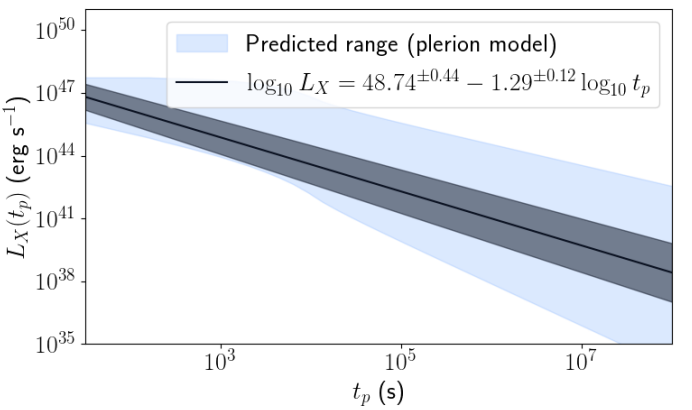

Fig. 2. X-ray plateau luminosity in the source frame $L_{\rm p} = L_{\rm X}(t_{\rm p})\,({\rm erg\,s^{-1}})$ versus X-ray plateau duration $t_{\rm p}$ (s). The black line and grey-shaded region correspond to the best-fit correlation from Ref. 18 from a sample of 159 GRBs. The light blue shaded region corresponds to the range of ($L_{\rm p}$, $t_{\rm p}$) pairs generated by the PWNe model for $B = 5.0 \times 10^{-1}\,{\rm G}$, $10^{12} \leq B_0/(1\,{\rm G}) \leq 10^{16}$, and $\Omega_0/2\pi \leq 10^3\,{\rm Hz}$. Model parameters were chosen based on results presented in Ref. 26.

4. Inferring Parameters of the Central Engine

In this section, we review results presented in Ref. 26 inferring B_0, Ω_0, $E_{\pm 0}$, a, and (for model B) B using the X-ray afterglow for six sGRBs of known redshift with an X-ray plateau. We reproduce here the necessary physics to interpret the results and leave the details of the analysis to Ref. 26.

The source-frame synchrotron spectrum at time t is

$$F_\nu(t,\nu) = N(E,t)\left.\frac{\mathrm{d}E}{\mathrm{d}t}\right|_{\mathrm{synch}}\frac{\mathrm{d}E}{\mathrm{d}\nu}. \tag{7}$$

The synchrotron cooling rate and the characteristic synchrotron frequency depend on the magnetic field in the bubble, which is determined by B_0 and Ω_0 in model A and by B in model B. The dependence on $N(E,t)$ indicates F_ν is dependent on B, B_0, Ω_0, $E_{\pm0}$, and a, so a single point-in-time spectrum is sufficient to infer posteriors on each parameter. For a full discussion of the results and method, see Sec. 4 in Ref. 26. For both models, one has a neutron star with an approximately millisecond spin period ($\Omega_0/2\pi \lesssim 10^3\,\mathrm{Hz}$) and a magnetar-strength poloidal magnetic field ($B_0 \sim 10^{15}\,\mathrm{G}$) i.e. a millisecond magnetar. The correlations between B_0 and Ω_0 reflect their relation to the spin-down luminosity $L_0 \propto B_0^2\Omega_0^4$ and $\tau \propto B_0^{-2}\Omega_0^{-2}$. For model B, the posteriors on B cover the range $10^{-1} \lesssim B/(1\,\mathrm{G}) \lesssim 1$. This is much stronger than the magnetic field in the interstellar medium ($\sim 10^{-6}\,\mathrm{G}$) but smaller than the expected field advected outwards from the central object by the relativistic outflow (i.e. the magnetic field in model A). For both models, $E_{-0} \sim 10^{-3}\,\mathrm{erg}$, which is consistent with a population of electrons accelerated in the magnetar's magnetosphere and injected into the magnetar wind with a radiation-reaction-limited Lorentz factor.

4.1. *Spectral evolution*

In this section, we review briefly results presented in Ref. 26 using the spectrum of GRB 130603B at four separate epochs to infer B_0, Ω_0, $E_{\pm0}$, a, and B for each epoch. We label each epoch t_i with corresponding magnetic field B_i for $i \in [1,4]$ and use log uniform priors such that $10^{-6} < B_i/(1\,\mathrm{G}) < 10^6$. For each epoch with flux data F_{ν_i}, flux uncertainty σ_i, and model flux $F_\nu(t_i,\nu)$ given by Eq. (7), we define a Gaussian likelihood $P_i \propto \exp\left\{\left[F_{\nu_i} - F_\nu\left(t_i,\nu\right)\right]^2 / \left(2\sigma_i^2\right)\right\}$ such that the priors on B_0, Ω_0, $E_{\pm0}$ and a are the same at each epoch. The analysis is performed on the joint likelihood $\Pi_i P_i$.

The median values of the posterior describe a millisecond magnetar with $B_0 \approx 2\times10^{15}\,\mathrm{G}$ and $\Omega_0/2\pi \approx 600\,\mathrm{Hz}$, supplying the remnant with relativistic electrons with $a \approx 1.9$, $E_{-0} \approx 3.2\times10^{-5}\,\mathrm{erg}$, and $E_{+0} \approx 1\,\mathrm{erg}$. The median magnetic fields B_i suggest the field drops at an average rate of $0.04\,\mathrm{G\,s^{-1}}$ from $B_1 = 2\times10^2\,\mathrm{G}$ at $t_1 = 643\,\mathrm{s}$ to $B_4 = 5\times10^{-1}\,\mathrm{G}$ at $t_4 = 5735\,\mathrm{s}$. This is both slower and weaker than what is expected for the field in the termination shock of the wind in model A, which scales roughly as $B(t) \propto B_0 t^{-2}$ for $t \gtrsim \tau$, if the wind expands at a constant, relativistic speed (as in Ref. 25). The scale and temporal evolution of the B_i indicate the time-dependent magnetic field in the bubble requires revision. Several mechanisms for this are discussed in Ref. 26, including varying the expansion rate of the bubble or choosing an entirely separate magnetic field configuration.

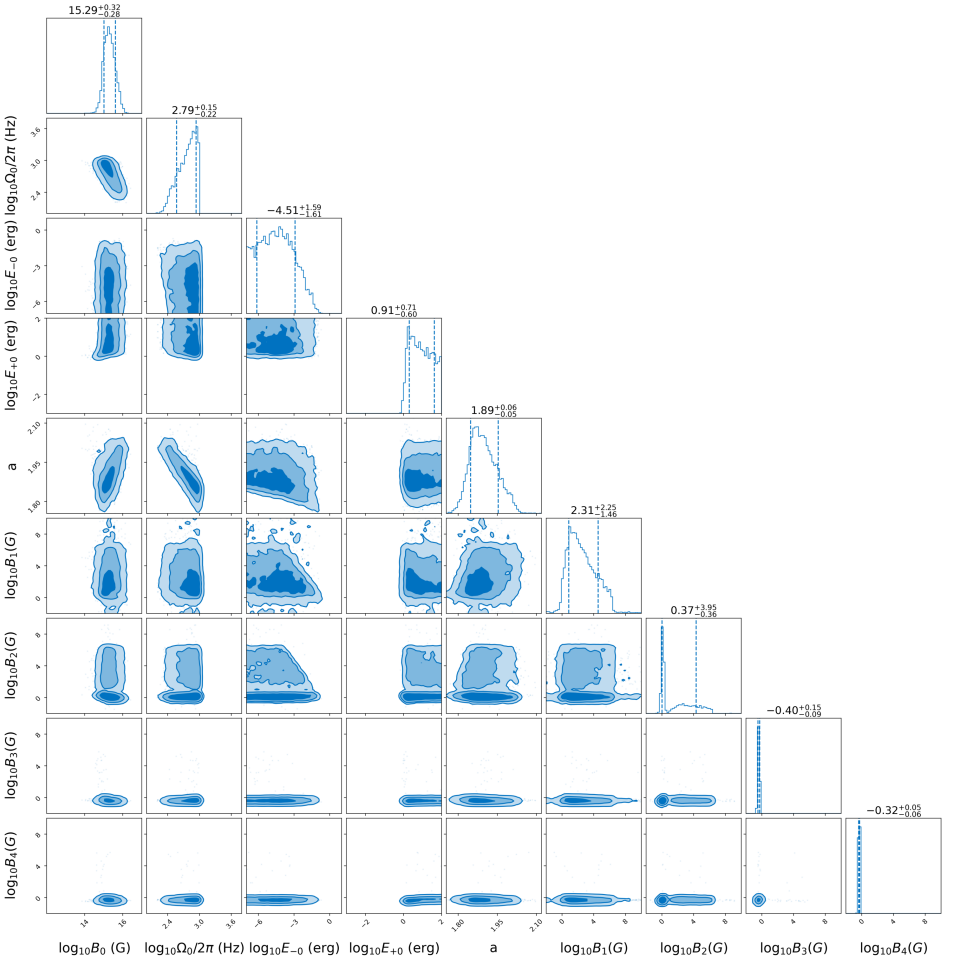

Fig. 3. Corner plot showing the posterior distribution obtained for four instantaneous spectra for GRB130603B for the parameters $\log_{10} B_0$ (G), $\log_{10} \Omega_0/2\pi$ (Hz), $\log_{10} E_{\pm 0}$ (erg), a, and $\log_{10} B_i$ $(1 \leq i \leq 4)$ (G). Figure reproduced from Ref. 26

5. Conclusion

A millisecond magnetar engine based on classic models of PWNe can explain some of the observed features of canonical sGRB afterglows. Plateau light curves are broadly consistent with the synchrotron output of an electron population $N(E, t)$ evolving under ongoing, power-law injection and adiabatic and synchrotron cooling. Such a model may be referred to as a plerion model (as in Ref. 25 and Ref. 26) or, as a synonym, a PWNe model (as we do in this work). The model is able to reproduce both the shape of the afterglow and correlations L_p–t_p. Furthermore, the instantaneous spectra can be used to infer B, B_0, Ω_0, $E_{\pm 0}$, and a within the context of the model. However, the model summarized here (originally in Ref. 25)

is highly idealized and does not include the important effects of merger ejecta on the evolution of the remnant (considered in e.g. Refs. 20–22). Also, as presented in Ref. 26, the temporal evolution of the spectrum implies a magnetic field that is inconsistent with both a dipole field (model A) and a constant field (model B). Future modeling improving on the work in Ref. 25 and integrating it into existing models for sGRB remnants should ultimately be compared to a broad sample of sGRBs.

Strange quark matter (SQM) may be the true ground state of matter. According to this SQM hypothesis, the observed neutron stars actually should all be strange quark stars. But distinguishing between neutron stars and strange quark stars by means of observations is extremely difficult. It is interesting to note that under the SQM hypothesis, less massive objects such as strange quark planets and strange dwarfs can also stably exist. The extremely high density and small radius of strange quark planets give us some new perspectives to identify SQM objects and to test the SQM hypothesis. First, the tidal disruption radius of strange quark planets is much smaller than normal planets, so, very close-in exoplanets can be safely identified as candidates of SQM objects. Second, gravitational waves (GW) from mergers of strange quark star-strange quark planet systems are strong enough to be detected by ground-based GW detectors. As a result, GW observation will be a powerful tool to probe SQM stars. At the same time, the tidal deformability of SQM planets can be measured to further strengthen the result.

Keywords: Strange quark stars, Exoplanets, Gravitational waves, Neutron stars

1. Introduction

The central engine of gamma-ray bursts may be compact objects such as neutron stars. However, our knowledge about matter under extreme densities is still quite poor so that the internal composition and structure of neutron stars are largely uncertain to us.[1] It has been argued that the energy per baryon of strange quark matter (SQM), which is composed of three favors of quarks (up, down and strange quarks), could be less than normal hadronic matter. As a result, SQM may be the true ground state of matter.[2,3] If this hypothesis is true, then it is even possible that all the so called "neutron stars" observed in the Universe should actually be strange quark stars.[4,5]

However, it is difficult to distinguish between strange quark stars and neutron stars through current astronomical observations. For a long time, people have tried to find the difference between neutron stars and strange quark stars in terms of mass-radius relationship, cooling rate, the minimum spin period and gravitational

wave (GW) features. But for a typical 1.4 $M_\odot$ compact object, the radius difference between a neutron star and a quark star is too small to be detected through current observational technology. Recently, Geng et al pointed out that fast radio busts may originate from the collapses of the crust of strange quark stars.[6,7] It provides an novel visual angle on these interesting objects.

It is interesting to note that, under the SQM hypothesis, quark matter is bounded by strong interaction but not gravity.[5] So, SQM can even exist stably in the form of small chunks in the universe. It implies that planets composed of strange quark matter can also exist stably.[8,9] Strange quark planets are very different from normal planets. They have a much higher mean density and a much smaller radius, which provide us with some effective new methods to test the SQM hypothesis. In our previous studies, we have suggested some new methods to identify strange quark planet.[10–15] In this article, we will summarize the results.

2. Searching for strange quark planets among close-in exoplanets

Planets cannot be too close to their host stars, otherwise they will be tidally broken up by the strong tidal force of their hosts. We can use the tidal disruption radius r_{td} to describe the shortest possible separation between a planet and its host, which can be analytically expressed as[16]

$$r_{td} \approx \left(\frac{6M}{\pi\bar{\rho}}\right)^{\frac{1}{3}}, \tag{1}$$

where M is the mass of the host star and $\bar{\rho}$ is the mean density of the planet. For the convenience of calculation, this equation can be further written as,

$$r_{td} \approx 2.37\times10^{6}\left(\frac{M}{1.4\mathrm{M}_\odot}\right)^{\frac{1}{3}}\times\left(\frac{\bar{\rho}}{4\times10^{14}\mathrm{gcm}^{-3}}\right)^{-\frac{1}{3}}\mathrm{cm}. \tag{2}$$

Suppose a planet orbits around a host star which has a typical mass of 1.4 $M_\odot$. For a strange quark planet, its mean density can be as high as 4×10^{14} g cm^{-3}. With such a high density, the r_{td} of the strange quark planet will be less than 2.37×10^{6} cm, which is only about twice the radius of a pulsar.[10,11] But for normal matter planets, the density is on the order of ~ 8 g cm^{-3}, and the corresponding r_{td} is generally larger than 8.7×10^{10} cm. Even if we take the mean density as 30 g cm^{-3}, which is already a very high value for normal matter, the derived r_{td} will still be larger than 5.6×10^{10} cm.[10,11] From these simple calculations, we argued that if the orbital radius of a planet is found to be less than 5.6×10^{10} cm, then the planet should be a strange quark planet.

An extremely close-in strange quark planet cannot be observed directly by imaging method. On the contrary, it can be relatively easily detected via pulsar timing observations. According to Kepler's law, the relationship between the orbital radius and the period can be expressed as

$$\frac{a^3}{P_{\mathrm{orb}}^2} \approx \frac{GM}{4\pi^2}, \tag{3}$$

where G is the gravity constant, a is the orbital radius and $P_{\rm orb}$ is the planet's orbital period. For planets with a smaller than $\sim 5.6 \times 10^{10}$ cm, the orbital period will be less than ~ 6100 s. Therefore, it is argued a planet with the orbital period less than 6100 s should be a strange quark planet.[10,11]

Using the above criterion, Kuerban et al. have tried to search for strange quark planets among exoplanets, especially among pulsar planets.[15] According to their results, the short period pulsar planets of PSR J0636 b, PSR J1807-2459A b and PSR 1719-14 b are good candidates of strange quark planets.

3. Searching for strange quark planets through GW observations

Since 2015, gravitational wave observations have opened a new window for astronomy[17] and are also expected to be a new tool for searching for quark stars.[18] Note that it is still quite difficult to distinguish between binary neutron star mergers and binary quark star mergers by gravitational wave observations, because these two kinds of compact stars have marginal difference in radius at the typical mass of 1.4 $M_\odot$.[19,20] However, gravitational waves may bring new opportunities in searching for strange quark planets.

A normal matter planet can not be too close to its host, otherwise it will be tidally disrupted. Consequently, the gravitational wave emissions from normal planetary systems are usually too weak to be detected. But due to the extremely high density and the very close-in orbit of strange quark planets, a strange star-strange planet system can produce very strong gravitational wave emissions, especially at the final stage of the merging process. If such a merger event occurs in the local universe, it would be detectable for the gravitational wave detectors such as Advanced LIGO and the Einstein Telescope.[12]

GW observations can also help diagnose the internal composition and internal structure of compact stars by means of tidal deformability measurements. The first tidal deformability measurement has been obtained for the binary neutron star merger event of GW170817, which gives a new constraint on the equation of state of dense matter.[21,22]

Tidal deformability is a quantity that describes the deformation of a star in a tidal field, which is defined as

$$\lambda = -\frac{Q_{ij}}{E_{ij}}, \tag{4}$$

where Q_{ij} is the induced quadrapole moment of the star and E_{ij} is the tidal field that it resides in (i.e., the gravity field produced by its companion). For convenience, this quality is often written in a dimensionless form, i.e.,

$$\Lambda = \frac{\lambda c^{10}}{G^4 m^5}. \tag{5}$$

Here, c is the speed of light in vacuum and m is the mass of the star.

Generally speaking, a larger tidal deformability means that the star will be relatively easier to be deformed in a tidal field.[22] So, tidal deformability will affect

the evolution of the gravitational wave phase, which could be perceived in GW observations.[13] Comparing the observed tidal deformability with that calculated by solving the Tolman-Oppenheimer-Volkoff equation adopting a particular equation of state (EoS), we can get useful information on the internal structure of compact stars.[23,24]

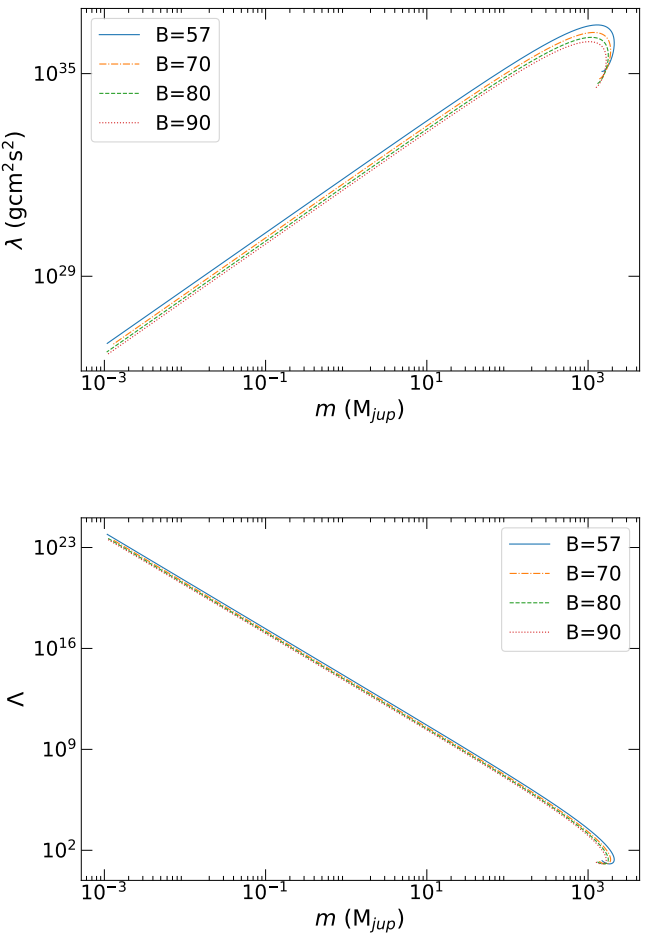

Fig. 1. Tidal deformability (the upper panel) and dimensionless tidal deformability (the lower panel) versus mass for strange quark stars and strange quark planets.[13] Different line styles represent different bag constant, which is marked in the figure in units of MeV/fm^3.

Following the method of Hinderer et al.,[23,24] we have calculated the tidal deformability of strange quark stars, paying special attention on strange dwarfs and strange planets. We engage the bag model for strange quark matter.[4] Our results are shown in Figure 1. We see that as the mass decreases, the value of the deformability also decreases, while the value of the dimensionless tidal deformability keeps

increasing. For a planet with a mass of $10^{-3}M_{\rm jup}$, its tidal deformability is up to $\sim 10^{27}$ g cm^2 s^2 and its dimensionless tidal deformability is up to $\sim 10^{23}$, which are much higher than those of normal matter planets. Therefore, the tidal deformability is a useful parameter for identifying strange quark planets.[13]

4. Summary

Discriminating between neutron stars and strange quark stars is a challenging task. In this article, we try to solve the problem from a novel point of view. We mainly concentrate on strange quark planets. It is suggested that there are basically two methods to search for strange quark planets. First, we can try to find close-in pulsar planets with the orbital period less than 6100 s. Encouragingly, at least three possible strange quark planet candidates have been found. Second, we can identify strange quark planets through gravitational wave observations. It is found that the mergers of strange star-strange planet systems can produce strong gravitational wave bursts, which can potentially be detected by the advanced LIGO and the future Einstein Telescope. The tidal deformability of strange quark dwarfs and strange quark planets is specially calculated. In short, we stress that strange quark planets could be a powerful tool for clarifying the nature of the so called "neutron stars".

Gamma-ray Bursts (GRBs) are promising tools to probe the Universe. Especially, we can get constraints on cosmological parameters with the help of GRB luminosity relations. Recently, a tight L-T-E relation has been found. This relation involves a special subclass of GRBs, i.e., GRBs have X-ray plateaus in their X-ray afterglows. The isotropic γ-ray energy of the prompt GRB ($E_{\gamma,\rm iso}$) are linked with the duration of the plateau phase (T_a) and the X-ray luminosity at the end of the plateau phase (L_X) through this relation. Beside this relation, we find that L_X and T_a also relate to the spectral peak energy ($E_{\rm p}$) and we call this relation the L-T-$E_{\rm p}$ relation. When using these relations to constrain the cosmological parameters, we find the L-T-E relation is insensitive to the cosmological parameters and both of these relations suffer from redshift evolution. We manage to correct the redshift evolution and use the de-evolved L-T-$E_{\rm p}$ relation to constrain the cosmological parameters. We get the best-fit result as $\Omega_m = 0.389^{+0.202}_{-0.141}$ (1σ) for the flat ΛCDM model. Our result is consistent with that from other probes within 1σ confidence level. Joint constraint on cosmological parameters is presented.

Keywords: Cosmology: dark energy – gamma-ray burst: general – stars: neutron

1. Introduction

Gamma-ray Bursts (GRBs) are extremely high-energy events. The multiband observation of the GRB afterglows has helped us to better understand the true nature of GRBs. Also, the observation of the early afterglow has showed that some GRBs have a plateau phase in their X-ray afterglow. The plateau phase is often thought to be connected with extra energy injection, possibly by a millisecond magnetar as the central engine.[1–3] It is interesting to note that these compact magnetars might actually be strange quark stars.[4]

Since GRBs have a cosmological origin, we can use them as a cosmological probe. The most important application is to constrain the cosmological parameters. The method is very similar to using Supernovae Ia (SNe Ia).[5–7] We need solid luminosity relations to help us convert GRBs to standard candles.[8,9] Compared with using SNe Ia, the gamma photon from GRBs does not suffer from the extinction while they travel through the space.[10]

Several interesting relations are found for GRBs with X-ray plateau. Dainotti et al. (2008) first found a nearly anti-relation between the X-ray luminosity at the end time of the plateau (L_X) and the duration of the plateau phase at the rest frame (T_a).[11,12] This relation is also known as the Dainotti relation. The L-T-E relation

found by Xu & Huang links L_X and T_a together with the isotropic γ-ray energy of the prompt GRB ($E_{\gamma,\rm iso}$).[2] Recently, Tang et al. (2019) have revisited this relation with a sample of 174 GRBs and found $L_X \propto T_a^{-1.01} E_{\gamma,\rm iso}^{0.84}$.[13] Meanwhile, a fundamental plane relation was established by Dainotti et al. (2016) which connect L_X, T_a, and $L_{\rm peak}$.[14] Using class-specific GRB samples, these three parameters were very closely connected with each other.[15] Also, a four parameter Combo-relation was recently established which involves α, L_X, T_a, and $E_{\rm p}$, where α is the power-law timing index of the afterglow in its normal decay phase and $E_{\rm p}$ is the spectral peak energy.[16,17] Meanwhile, we have found a new relation between L_X, T_a, and $E_{\rm p}$, which we call the L-T-$E_{\rm p}$ relation.[18] These relations are extensions of the Dainotti relation and reveal the connection between the property of the X-ray plateau with the early prompt emission.

In this paper, we first check the possibility of using the L-T-E relation to constrain the cosmological parameters. We then present the new L-T-$E_{\rm p}$ relation and constraints on the cosmological parameters.

2. Difficulty of using the L-T-E relation to probe the Universe

The L-T-E relation can be written as

$$\log \frac{L_X}{10^{47}{\rm erg/s}} = a + b \log \frac{T_a}{10^3{\rm s}} + c \log \frac{E_{\gamma,\rm iso}}{10^{53}{\rm erg}}. \quad (1)$$

We use the Markov chain Monte Carlo (MCMC) algorithm to get the best-fit with the same sample provided by Tang et al. (2019)[13] and obtain $a = 1.60 \pm 0.06$, $b = -1.01 \pm 0.05$, $c = 0.85 \pm 0.04$ and $\sigma_{\rm ext} = 0.40 \pm 0.03$, i.e., $L_X \propto T_a^{-1.01\pm0.05} E_{\gamma,\rm iso}^{0.85\pm0.04}$. $\sigma_{\rm ext}$ is the the extrinsic scatter parameter arouse from some hidden variables.

When using GRBs to constrain the cosmological parameters, a solid luminosity relation that works at all redshift is needed. Hence, we divide the full sample into four redshift bins and check the evolution of the coefficients. We find that the coefficients of this relation vary a lot among different redshift bins, especially in the coefficient "c". So the L-T-E relation suffers from the redshift evolution. More importantly, because both L_X and $E_{\gamma,\rm iso}$ are related to cosmological parameters through the same dependence on the luminosity distance, so the cosmological effect is canceled out in this relation. In other words, this relation is insensitive to cosmological parameters.

3. Cosmology with the L-T-E$_{\rm p}$ relation

We have found a new relation connects L_X, T_a, and $E_{\rm p}$. We call it the L-T-$E_{\rm p}$ relation and it follows $L_X \propto T_a^{-1.08\pm0.08} E_{\rm p}^{0.76\pm0.14}$ using our sample of 121 GRBs.[18]

Likewise, we check whether this relation suffers from redshift evolution. In fact, this relation indeed evolves with redshifts. We think of two solutions to remove the evolution from this relation. The first solution is trying to find out the redshift

evolution in each parameter (i.e., L_X, T_a, and $E_{\gamma,\rm iso}$) which will be described in Section 3.1. The second one is simply adding an evolution term to account for the redshift evolution in the whole relation and the details of this solution is presented in Section 3.2.

3.1. *Redshift evolution in each parameter*

Following the Efron & Petrosian method,[19] we get the redshift evolution of L_X, T_a, and $E_{\rm p}$ separately. A simple power-law function $(1+z)^k$ is used as the evolution form of each parameter.[20] Our best-fit results are $k_{L_X} = 3.38 \pm 0.62$, $k_{T_a} = -1.54 \pm 0.30$, and $k_{E_{\rm p}} = 0.75 \pm 0.25$.[18]

After correcting for the redshift evolution of each parameter, we can get a new separate de-evolved L-T-$E_{\rm p}$ relation as

$$\log \frac{L_X/(1+z)^{k_{L_X}}}{10^{47}{\rm erg/s}} = a''' + b''' \log \frac{T_a/(1+z)^{k_{T_a}}}{10^3{\rm s}} + c''' \log \frac{E_{\rm p}/(1+z)^{k_{E_{\rm p}}}}{\rm keV}. \quad (2)$$

3.2. *Redshift evolution of the whole relation*

To get the redshift evolution of the whole relation, we simply put the possible evolution in a single power-law term of $(1+z)^{d'}$,[21] and the L-T-$E_{\rm p}$ relation can be re-written as

$$\log \frac{L_X}{10^{47}{\rm erg/s}} = a' + b' \log \frac{T_a}{10^3{\rm s}} + c' \log \frac{E_{\rm p}}{\rm keV} + d' \log(1+z). \quad (3)$$

With the MCMC method, we get the best-fit result of parameter d', which is $d' = 1.78 \pm 0.29$.[18] Then we move the evolution term to the left side of Equation 3 and get a de-evolved L-T-$E_{\rm p}$ relation

$$\log \frac{L_{X,\rm cal}}{10^{47}{\rm erg/s}} = a'' + b'' \log \frac{T_a}{10^3{\rm s}} + c'' \log \frac{E_{\rm p}}{\rm keV}, \quad (4)$$

where $L_{X,\rm cal} = L_X/(1+z)^{d'}$.

3.3. *Constraints on cosmological parameters*

With the two de-evolved relations we get above, we can now safely use them to probe the Universe. We fix $H_0 = 70.0$ km s^{-1} Mpc^{-1} for simplicity. When using GRBs to constrain the cosmological parameters, one may face the so-called "circularity problem".[22] Here we consider two methods to avoid this problem. The first method is the "simultaneously fitting method" which means to fit the relation coefficients together with the cosmological parameters.[23] The second is the "standardize with SNe Ia method" which means to use SNe Ia data set as calibrators to calculate the luminosity distances of GRBs independently from cosmological models.[8]

With the separate de-evolved L-T-$E_{\rm p}$ relation, we perform the simultaneously fitting method and get $\Omega_m = 0.76^{+0.17}_{-0.26}$ for the flat ΛCDM model.

As for the de-evolved L-T-$E_{\rm p}$ relation, we first perform the simultaneously fitting method. The best-fit result is $\Omega_m = 0.71^{+0.20}_{-0.28}$ for the flat ΛCDM model. Then we use the standardize with SNe Ia method with the "Pantheon sample" of SNe Ia.[24] We plot a Hubble diagram for GRBs, as shown in Figure 1. The low-redshift sample is calibrated by the "Pantheon sample" and shows little dispersion, while the large dispersion of the high-redshift GRB distance modulus comes from the uncertainty of the GRB relation. With the calibrated distance modulus of the high-redshift GRBs, we get the best-fit result as $\Omega_m = 0.389^{+0.202}_{-0.141}$ for the flat ΛCDM model. Also we get $\Omega_m = 0.333^{+0.188}_{-0.142}$ and $\Omega_\Lambda = 0.346^{+0.356}_{-0.249}$ for the non-flat ΛCDM model and $\Omega_m = 0.369^{+0.217}_{-0.191}$ and $w = -0.966^{+0.513}_{-0.678}$ for the flat wCDM model.

Then, we compare these results with those from other probes (i.e., SNe Ia, CMB, BAO) and find that they are consistent with each other in 1σ confidence level. Also, together with other probes, we even get a more accurate constraint on the cosmological parameters. We get $\Omega_m = 0.289 \pm 0.008$ and $\Omega_\Lambda = 0.710 \pm 0.006$ for the non-flat ΛCDM model with all the four probes. As for the flat Universe, combining the four probes, we obtain $\Omega_m = 0.295 \pm 0.006$ and $w = -1.015 \pm 0.015$ under the wCDM model and $\Omega_m = 0.291 \pm 0.005$ for the ΛCDM model. Figure 2 shows the fitting results with different probes under the flat ΛCDM model.

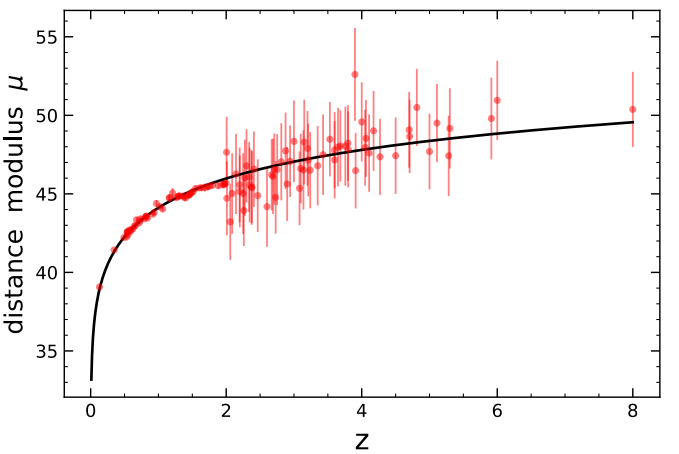

Fig. 1. Calibrated GRB Hubble diagram from the de-evolved L-T-$E_{\rm p}$ relation.[18] Red points represent our GRB sample and the black line is the theoretical distance modulus calculated with $H_0 = 70.0$ km s^{-1} Mpc^{-1} and $\Omega_m = 0.289$ under the flat ΛCDM model.

4. Summary

In our work we find that the previous L-T-E relation is not a good probe for cosmology and it is possible to use the L-T-$E_{\rm p}$ relation as a probe. We want to

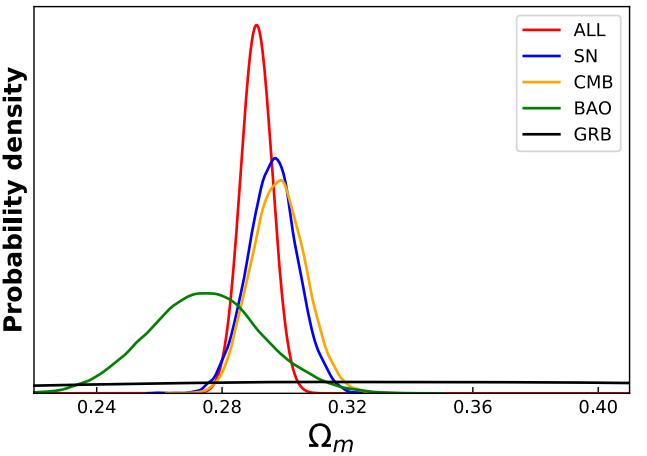

Fig. 2. Under the flat ΛCDM model, we get the probability density on Ω_m with observational data of SNe Ia (blue), CMB (orange), BAO (green), and the de-evolved L-T-$E_{\rm p}$ relation of GRBs (black). The joint constraint from all the four probes is $\Omega_m = 0.291 \pm 0.005$ (red).

stress that possible redshift evolution in GRB relations need to be removed before they can be used as cosmological probe. From our study, we can see that it is hard to get good constraints with GRBs alone, because of the large dispersion in GRB relations. However, with the improvement of GRB observations, we may tighten these relations in the future.

The actual knowledge of the structure and future evolution of our universe is based on the use of cosmological models, which can be tested through the so-called 'probes', namely astrophysical phenomena, objects or structures with peculiar properties that can help to discriminate among different cosmological models. Among all the existing probes, of particular importance are the Supernovae Ia (SNe Ia) and the Gamma Ray Bursts (GRBs): the former are considered among the best standard candles so far discovered but suffer from the fact that can be observed until redshift $z = 2.26$, while the latter are promising standardizable candles which have been observed up to $z = 9.4$, surpassing even the farthest quasar known to date, which is at $z = 7.64$. The standard candles can be used to test the cosmological models and to give the expected values of cosmological parameters, in particular the Hubble constant value. The Hubble constant is affected by the so-called "Hubble constant tension", a discrepancy in more than 4 σ between its value measured with local probes and its value measured through the cosmological probes. The increase in the number of observed SNe Ia, as well as the future standardization of GRBs through their correlations, will surely be of help in alleviating the Hubble constant tension and in explaining the structure of the universe at higher redshifts. A promising class of

*Corresponding author

GRBs for future standardization is represented by the GRBs associated with Supernovae Ib/c, since these present features similar to the SNe Ia class and obey a tight correlation between their luminosity at the end of the plateau emission in X-rays and the time at the end of the plateau in the rest-frame.

Introduction

Modern cosmology is based on the so-called ΛCDM model: this is the standard cosmological model based on the Cold Dark Matter (CDM) and containing the cosmological constant Λ that describes the dark energy contribution to the expansion of the cosmos. This model has been widely accepted in the scientific community and can predict the accelerated expansion of the universe, as proved by the outstanding works of Riess et al. (1998)[1] and Perlmutter et al. (1999)[2] where this effect was demonstrated through the use of SNe Ia. Despite being well received, the ΛCDM suffers from some open problems, in particular the Hubble constant (H_0) tension. This is the discrepancy, in more than 4 σ, between the value of H_0 measured with local probes (Cepheids and SNe Ia) and the value obtained through the Cosmic Microwave Background (CMB) radiation data measured by the Planck satellite. To solve this issue, many approaches have been proposed (alternative cosmological models, refined measurements of H_0, etc.), but it is necessary to use reliable probes for testing the cosmological models. From this perspective, the so-called standard candles are very important: these are astrophysical objects or events which have a fixed luminosity or that obey an intrinsic relation between the luminosity and some of the other parameters that do not depend on the luminosity themselves. To date, different objects have been standardized, in particular the SNe Ia which have a nearly uniform peak luminosity, but the problem is that these can cover only a relatively small range of redshifts: the farthest SN Ia so far observed has a redshift of $z = 2.26$.[3] The GRBs may have a key role in the future development of cosmology since they have been observed at higher redshifts than SNe Ia and quasars (currently the farthest quasar being at redshift 7.64[4]) and are able to further extend the Hubble diagram (the distance moduli versus the redshift). A particular class of GRBs, the GRBs with a plateau emission (namely, a relatively flat section of the lightcurve that follows the prompt emission and precedes the afterglow, observed not only in X-rays and optical but also in γ-rays[5]), has proven to be a promising standardizable candle through the application of tight correlations among the GRB lightcurve properties, such as the intrinsic and unbiased correlation between the luminosity at the end of the plateau emission in the X-rays, L_X, with the time at the end of the plateau emission in the rest-frame, T_X^* [6–13] (which was later confirmed also in the optical[14]) and the unbiased one between L_X and the 1s peak prompt luminosity, L_{peak}.[15,16] A combination of these two correlations led to the so-called 3D fundamental plane relation, namely a tight correspondence between L_X, T_X^*, and

L_{peak}.[17–19] For a review of these correlations, see Dainotti & Del Vecchio (2017),[20] Dainotti et al. (2018a,2018b),[21,22] and Dainotti (2019).[23] The GRB correlations are not only useful as cosmological tools, but also as discriminant among theoretical models to explain the GRBs origin, emission mechanism, and the nature of their environment.[24–29] In particular, the plateau emission and the correlations that involve its properties strongly suggest how the typical magnetic fields and spin periods of the magnetars (namely, a fast rotating neutron star) could explain the plateau emission itself (Rowlinson et al. 2014).[25] In a later paper, Rea et al. (2015)[26] show that the magnetar model can be reconciled within the GRB emission in the plateau only if supermagnetar with high magnetic field strengh are allowed. In a successive paper of Stratta et al. (2018)[30] for the first time a non-ideal modelling of spindown magnetar is fitted to the afterglow data with a statistical sample of 40 Long GRBs (LGRBs) with a well-defined plateau and 13 Short GRBs (SGRBs) including the short with extended emission. The conclusion reached in that paper is that SGRBs including the SGRBs with Extended Emission (SEE) and LGRBs can be explained within the magnetar model but with the difference that the LGRBs occupy a lower end in the magnetic field-spin period plane compared to the SGRBs which present a higher spin, P, and a higher magnetic field, B. The correlation between magnetic field and spin period follow the established physics of the spin-up line for accreting neutron star in Galactic binary systems. The B−P relation obtained perfectly matches spin-up line predictions for the magnetar model with mass accretion rates expected in the GRB prompt phase. The latter are $\sim$ 1114 orders of magnitude higher than those inferred for the Galatic accreting NSs. Thus, correlations are useful to cast more light on the physics of GRBs and this represents an effective support towards the future standardization of these transient phenomena. The current proceeding focuses on two main topics concerning cosmology with SNe Ia and GRBs: (1) the investigation of the H_0 tension through a binning approach on the Pantheon sample of SNe Ia[31] and (2) the use of the GRB fundamental planes in optical and X-ray as cosmological distance indicators and the discussion of their future use as standardizable candles.

1. On the Hubble constant tension in the SNe Ia Pantheon sample

The H_0 tension is the discrepancy in more than 4 σ between the value of H_0 estimated with local probes, such as SNe Ia and Cepheids ($H_0 = 74.03 \pm 1.42$ km $s^{-1}Mpc^{-1}$), and the value of H_0 obtained with the Planck Cosmic Microwave Background (CMB) radiation ($H_0 = 67.4 \pm 0.5$ km $s^{-1}Mpc^{-1}$). It represents one of the most important open problems in modern cosmology. To investigate it, we divided the Pantheon sample (Scolnic et al. 2018[32]), a collection of 1048 spectroscopically confirmed SNe Ia, into 3, 4, 20, and 40 bins ordered in redshift. In our analysis, we considered two cosmological models: the standard ΛCDM model and the w_0w_aCDM model, where the equation of state parameter is expressed according to the Chevallier-Polarski-Linder parametrization ($w(z) = w_0 + w_a * z/(1 + z)$).[33,34]

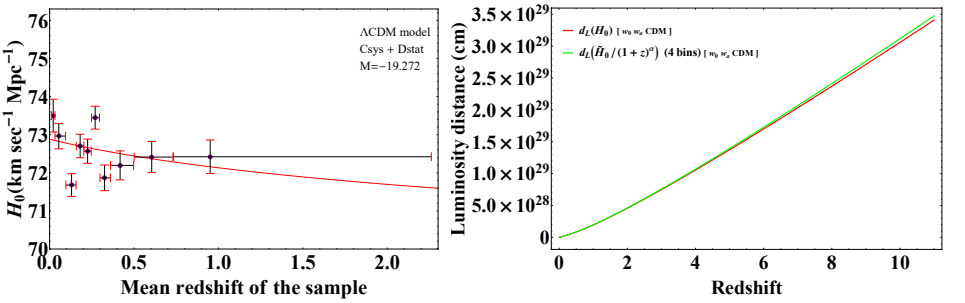

Fig. 1. **Left panel.** The fitting of the H_0 values with redshift in the case of 10 bins of SNe, assuming the ΛCDM model, using the full covariance matrix composed of systematic (C_{sys}) and statistical (D_{stat}) uncertainties,[32] and fixing $M = -19.272$ such that $H_0 = 73.5km\ s^{-1}\ Mpc^{-1}$ in the first bin. The slow decreasing trend is plain to see. **Right panel.** The comparison between the luminosity distance formula corrected with the $g(z)$ (in green) and the luminosity distance given by the standard w_0w_aCDM model (in red) as functions of the redshift.

Due to the degeneracy between the H_0 and the fiducial absolute magnitude of SNe Ia, M, we set M in such a way that locally the $H_0 = 73.5km\ s^{-1}\ Mpc^{-1}$. The fiducial values of the total matter density parameters have been assumed as $\Omega_M = 0.298$ (for the ΛCDM model) and $\Omega_M = 0.308$ (for the w_0w_aCDM model). Considering both the cosmological models, for each bin in the 3, 4, 20, and 40 divisions we performed a χ^2 minimization followed by a Monte Carlo Markov Chain simulation to obtain the best-fit H_0 values together with their 1 σ uncertainties. After obtaining these, we fitted them with the following functional form: $g(z) = H_0'/(1+z)^\alpha$, where H_0' is the value of the Hubble constant at $z = 0$ obtained with the fitting and α is the evolutionary parameter. We found that the H_0 in the Pantheon sample evolves slowly with the redshift, with an α coefficient in the order of 10^{-2} which is compatible with zero from 1.2 σ to 2.0 σ. For example, in the left panel of Figure 1 the case of fitting with 10 bins using the ΛCDM model is shown, while in the right panel a comparison between the standard luminosity distance in the w_0w_aCDM model and the corrected luminosity distance substituting H_0 with $g(z)$ is plotted. Despite the α coefficients being compatible with zero in 3 σ, the highlighted decreasing trend may affect the cosmological results. Indeed, a modification of the luminosity distance formula where H_0 is replaced with the $g(z)$ form shows how the modified luminosity distance curve departs significantly from the ΛCDM canonical one at redshift $z \sim 10$ (see the right panel of Figure 1). To check what would be the behavior of H_0 if the trend was real, we extrapolated its value from the fitting at the redshift of the most distant galaxy so far discovered ($z = 11.09$, Oesch et al. 2016[35]) and at the redshift of the last scattering surface ($z = 1100$). We obtained that the extrapolated value of H_0 at $z = 1100$ is compatible in 1 σ with the one obtained through the Planck CMB measurements. If we consider the discrepancy between the aforementioned values of H_0, namely (74.03 ± 1.42) and (67.4 ± 0.5) $kms^{-1}Mpc^{-1}$ and we compare it with the tension between the fitting values H_0'

(at $z = 0$) and $H_0(z = 1100)$, we find that our approach leads to alleviate the H_0 tension from 54% to 72% for the ΛCDM and the w_0w_aCDM models, respectively. Thus, we not only found a way to alleviate the Hubble tension, but we provided also a plausible explanation for the observed discrepancy between the values of H_0 coming from probes at different redshifts. The observed decreasing trend may be due to hidden astrophysical biases, selection effects, or even the evolution of SNe Ia lightcurve parameters, as pointed out in Nicolas et al. (2021)[36] where it was shown that the stretch parameter distribution of the Pantheon sample is affected by the drift with the redshift. If this is not the case, and the trend is real instead, the explanation for it may be found in the modified gravity theories. We propose that the $f(R)$ theories in the Jordan frame may explain the observed slow evolution of H_0. However, to prove if this trend is real or not, it is necessary to rely (a) on the future observations of SNe Ia through that will enrich the currently known samples of transient phenomena and (b) on the extension of the Hubble diagram up to redshift ranges that SNe Ia could not cover, thus calling for the use of high-z phenomena such as the GRBs.

2. Optical and X-ray GRB Fundamental Planes as Cosmological Distance Indicators

GRBs, being observed at very high-z (up to $z = 9.4$ so far[37]), have the potential to be employed as standardizable candles, extending the cosmological distance ladder beyond the redshift of SNe Ia. Therefore, we employ them to do so by first standardizing them using the 3D fundamental plane relation. 50 X-ray GRBs cut from a full sample of 222 define the platinum sample, and their corresponding fundamental plane parameter variables are determined by Monte Carlo Markov Chain sampling maintained by Gelman-Rubin statistical constraints. We use both the platinum sample and a well-defined sample of SNe Ia as a combination of probes to accurately constrain the matter content of the modern universe, Ω_M. To do so, the plane parameters are allowed to vary simultaneously with Ω_M within the chain sampling. We find our best results with the addition of a third probe, namely, Baryon Acoustic Oscillations (BAOs), given their reliability as standard rulers. The combination of these three probes allows us to constrain Ω_M to 0.306 ± 0.006, assuming a ΛCDM cosmology. Furthermore, we test, for the first time in this research field, the novel 3D optical correlation as the extension of the 3D fundamental plane in X-ray wavelengths as a cosmological tool and check its applicability compared to that of the confirmed X-ray relation. In doing so, we find that our optical GRB sample is as efficacious in the determination of Ω_M as the platinum X-ray sample. To increase the precision on the estimate of Ω_M, we consider redshift evolutionary effects to overcome common biases such as the Malmquist effect. We employ the reliable Efron & Petrosian (1992)[38] statistical method to ensure that the correlation is intrinsic to the GRB physical mechanics and not due to selection bias. It is by accounting for this that we decrease the intrinsic scatter on the X-ray plane by 44.4%, thus defining

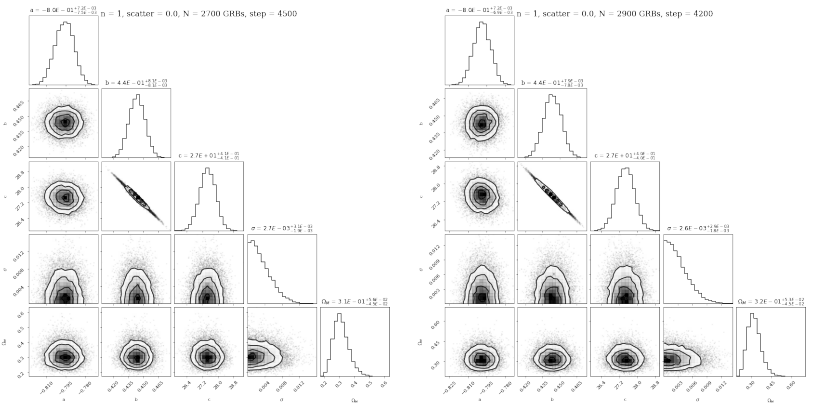

Fig. 2. **Left panel.** Contour plots with the parameters of the fundamental plane relation in X-rays (a, b, c) together with the intrinsic scatter σ and Ω_M, in the case of 2700 simulated GRBs with the evolution correction through the Efron & Petrosian method. **Right panel.** The same of the left panel, considering 2900 simulated GRBs.

the tightest 3D GRB correlation involving plateau features in the literature to date. Using this corrected sample, we confirm a value of 0.306 ± 0.006 defines Ω_M.

To both understand and predict the applicability of GRBs as standalone standard candles, we simulate additional GRBs to see how many are needed to reach uncertainties on Ω_M comparable to that of SNe Ia-derived values; we compare against Conley et al. (2011),[39] Betoule et al. (2014),[40] and Scolnic et al. (2018)[32] symmetrized error and standard deviation limits. In Figure 2, the contours for the parameters of the fundamental plane together with Ω_M after the Efron & Petrosian method application are shown in the case of 2700 (left) and 2900 (right) simulated GRBs. To do so, we first use both the full optical and X-ray GRB samples as independent bases for GRB simulation, conducted again by MCMC techniques. We find that the optical sample yields much smaller uncertainties on each simulation than the X-ray, and consequently a more constrained value of Ω_M. To increase this precision, we explore two methods of trimming our GRB sample leading to tighter planes that are in turn used as the base for simulation; an a posteriori trim using the smallest sample of GRBs for which the intrinsic scatter on the 3D plane which they defined remained near-zero, and an 'a priori' trim for which a number of possible sample sizes were tested and the one that yielded the best results after the fact is chosen. By simulating a large range of GRB sample sizes in both optical and X-ray wavelengths, we find by the construction of probability maps that the same precision as Betoule et al. (2014)[40] is achieved with only 376 simulated optical GRBs for which 47.5% of the fundamental plane variable error bars have been halved by a light curve reconstruction procedure. We find that the Conley et al. (2011)[39] limit is already achievable in most circumstances with current GRB numbers, and that the Scolnic et al. (2018)[32] limit is achieved for 1152 optical GRBs. Considering both

the detection power of future deep-space surveys THESEUS[30] and SVOM[41,42] and the nearing capability of machine learning approaches to extract unknown GRB redshifts, we conclude that GRBs will be as efficient standalone probes as SNe Ia by the year 2038. These results are interesting because, as the definition of GRBs as standard candles becomes more reliable with the introduction of the optical and X-ray fundamental planes, the addition of these astrophysical objects to SNe Ia and BAO data will soon give the most precise derivation of Ω_M ever achieved.

3. Summary and Conclusions

In this work, it was highlighted how and to what extent the GRBs may contribute to the cosmological analysis in the future. In the first part (1), the issue of the Hubble constant tension has been investigated with the Pantheon sample of SNe Ia, showing how the H_0 itself is characterized by a slowly decreasing trend with the redshift. This opens the discussion on the reason for this result: together with the possibility that a modified gravity theory could be an explanation, it is also likely that different selection biases persist in the observations of SNe Ia. This strongly suggests that the methods for biases correction, such as the Efron & Petrosian method, are needed in many astrophysical probes to achieve a reliable estimation of the cosmological parameters. Nevertheless, the limited coverage of redshift achieved by SNe Ia leads to the need for probes that can be observed at larger redshift. To this end, in the second part (2) it was shown how the 3D fundamental plane relation in the optical may help the future standardization of GRBs together with its counterpart in the X-rays. In addition, through the simulation of GRBs, it has been shown how this probe is a promising candidate to extend the Hubble diagram up to redshift greater than the ones of SNe Ia. Furthermore, a particular class of objects arouses much interest in the latest years, namely the class of LGRBs associated with Supernovae Ib/c (GRB-SNe): these manifest as supernovae appearing in the afterglow of the LGRBs and are very important since it was highlighted how the associated SNe obey a stretch-luminosity relation similar to the typical one of SNe Ia.[43] The physics behind their emission mechanism has been an object of study on several occasions[44–46] and one of the most interesting features of this class is that within the $L_X - T_X^*$ relation they show a Spearman correlation coefficient higher than the other subclasses of GRBs.[13] Thus, it is possible to use these events as a bridge between the properties of LGRBs and the ones of SNe Ib/c, giving a new perspective on the forthcoming standardization of GRB-SNe Ib/c. It is expected that the next observations of the new transients in the optical through the Subaru Telescope[47] and KISO Telescope[48] will help to investigate for selection biases and correct the current cosmological expectations on the evolution of the universe. Reliable testing of the cosmological models requires always new and more distant standardizable candles, and the GRBs have proven to be a reliable candidate for this purpose.

Theory of plateau phase in Gamma-Ray Bursts

Asaf Pe'er
Department of Physics, Bar Ilan University,
Ramat-Gan 52900, Israel
E-mail: asaf.peer@biu.ac.il
asafpeer2.ph.biu.ac.il/

Since its discovery in 2005, the plateau phase seen in the early x-ray afterglow of a significant fraction (10's of %) of GRBs confuse theoreticians. A close look reveals that "plateau" bursts nearly never show evidence for LAT emission, neither a strong thermal component. Using this a hint, I argue that the plateau is due to the coasting of GRB jets in a "wind"-like medius. I provide the theoretical arguments for the evolution of the lightcurve, and show how both the X-ray and optical lightcurves are naturally fitted within the framework of this model. The end of the plateau thus marks the transition between the coasting and the self-similar motion phases.

Keywords: Gamma rays: bursts; Jets: relativistic; X-rays

1. Introduction

Following the launch of the *Swift* satellite in 2004, it became obvious that the early afterglow x-ray lightcurve (minutes - hours) does not follow the previously expected self-similar decay seen at much later times. Rather, in about 60% of GRBs, a flat "plateau", lasting for $\sim 10^2 - 10^5$ s was observered in their x-ray lightcurve,[1,2] before it turns into the familiar self-similar decay, well modeled by the Blandford-McKee[3] solution.

Over the years, many attempts were made to explain this surprising result. Among the ideas discussed in the literature, are: (i) continuous energy injection that slows down the acceleration[1,4–6]; (ii) A two component jet model[7]; (iii) A forward shock emission in inhomogeneous media[8]; (iv) scattering by dust, or other modification of the ambient density by a gamma-ray trigger[9,10]; (v) A dominant reverse shock emission[11–13]; (vi) evolving microphysical parameters[9,14]; (vii) Viewing angle effect - jets viewed off-axis[8,15–17]; (viii) proto-magnetar that releases some of its energy at late times[18]; and (ix) forward shock emission, before the deceleration phase.[19] These plethora of models indicate the large uncertainty that exists in understanding this phenomenon. Furthermore, one thing in common for all these models, except for the last one, is that they all require some addition to the simple "fireball" model dynamics accompanied by synchrotron emission from shock-accelerated electrons.

The last suggestion, by Shen and Matzner[19] requires an explosion into a "wind" density profile (namely, $\rho(r) \propto r^{-2}$). It did not gain popularity, as (i) the deduced values of the Lorentz factor are lower than the 'fiducial' values, $\Gamma_i \gtrsim 100$; and (ii) the claim that this model can only account for a-chromatic afterglow, and can therefore

explain only a sub-sample of the GRB population.[20] As we show here, these two claims are incorrect.

2. Measuring GRB Lorentz factor: Is there a contradiction?

To day, there are three main methods used to estimate the Lorentz factor of the expanding GRB jets. The first relies on the opacity argument: in order to avoid copious production of pairs that would prevent observations of $>$ MeV emission one requires a high Lorentz factor. In particular, GeV emission seen by the LAT detector on board *Fermi* satellite in several bursts, require $\Gamma \gtrsim 100$.[21–24]

The second method requires identification of the onset of the self-similar expansion phase, which is accompanied by the formation and propagation of a reverse shock. For plausible parameters, emission from the reverse shock is expected mainly in the optical band, and thus an optical flash is considered as an indication for the transition to a self-similar motion. The time of this transition depends on the initial Lorentz factor, and is used to deduce its value.[25–29]

A third method of inferring the initial Lorentz factor is from quantifying the properties of the thermal emission (temperature and flux) observed during the prompt phase in a significant fraction of bright GRBs.[30–33] Indeed, within the framework of the classical GRB "fireball" model, a thermal component is unavoidable, as deep in the flow it is optically thick. The key is the adiabatic losses of the photons until they escape the plasma at the photosphere. If the photospheric radius is not much above the coasting radius, the thermal photons do not lose a large fraction of their energy, and a thermal component can be identified.[34]

In order to examine this issue, we looked at the 2^{nd} *Fermi* catalogue.[35] Out of 186 GRBs in this catalogue, only 3 show evidence for a shallow decay phase in the LAT data[36]; only one (the hard-short GRB 090510) show any evidence for a decaying plateau in the *Swift*-XRT data. However, for this specific burst, the X-ray slope during the early afterglow ($0.69^{+0.05}_{-0.06}$) can only marginally identify it as having a plateau. We therefore conclude that for bursts that show high energy emission, no evidence for a plateau phase exists.

We next looked at bursts which show evidence for a strong thermal component, and appeared in.[37–39] Non of these showed any evidence for an X-ray plateau. Finally, we looked at bursts which we were interested in analyzing. These are bursts that do show evidence for an x-ray plateau, and for which the redshift is known, and optical data is available. Non of these bursts showed any evidence for a thermal emission during their prompt phase, or for high energy ($>$ MeV) emission. We thus conclude that for bursts which show a plateau in their x-ray lightcurve, there is no indication for a high initial Lorentz factor, of $\Gamma_i \gtrsim 100$'s.

3. Dynamics and radiation

Within the context of the GRB "fireball" model, the expanding plasma jet undergoes 3 phases[40–42]: (i) an initial acceleration phase; due to light aberration, this phase

is observed to last only a fraction of a second. (ii) A coasting phase, in which the Lorentz factor of the flow is approximately constant. For "typical" GRB parameters, this phase lasts ∼few seconds. (iii) After the expanding plasma collects sufficient mass from the ambient medium (ISM), $m_{ISM} \gtrsim M_{ej}/\Gamma_i$, ($M_{ej}$ is the initially ejected mass), the flow begins its self-similar decay phase, which is well described by the Blandford-McKee[3] self-similar solution. During this phase, the Lorentz factor of the flow gradually decays. This is the phase responsible for the late time afterglow emission.

Once the flow becomes optically thin, the main radiation mechanism is synchrotron emission. Here we focus on emission from electrons accelerated to a power law distribution by the forward shock that exists in all phases, though we particularly focus on the coasting phase (ii) and late afterglow phase (iii). The accelerated electrons assume a power law distribution with power law index, p ($N_{el}(\gamma)d\gamma \propto \gamma^{-p}$). The resulting spectra is a well-known broken power law,[43,44] with 2 characteristic frequencies (omitting discussion on the self-absorption frequency, which is below the optical band is thus not relevant for the analysed signal): the peak frequency, $\nu_m^{ob.} \propto \Gamma B \gamma_{el}^2$, and the cooling frequency, $\nu_c^{ob.} \propto \Gamma^3/(B^3 r^2)$. Here, Γ is the jet (bulk) Lorentz factor, B is the magnetic field, γ_{el} is the characteristic Lorentz factor of the accelerated electrons (the minimum Lorentz factor above which a power law distribution exists), and r is the emission radius. The characteristic emission frequency of the electrons accelerated by the forward shock is ν_m, and ν_c is obtained by equating the radiative cooling time to the dynamical time. A third parameter, N_e is the total number of radiating electrons, is needed to determine the total observed flux (for bursts with known redshift).

The global spectral and temporal shapes depend on whether the cooling frequency ν_c is above or below the peak frequency, ν_m. When $\nu_c < \nu_m$ the system is in the "fast cooling" regime, where electrons lose nearly all of their energy within the dynamical time, and when $\nu_c > \nu_m$ it is in the "slow cooling". At a given observed frequency ν, there are therefore 6 possible regions, summarized as follows and marked [A] – [F]:

- "Fast cooling", $\nu_c < \nu_m$:

$$F_\nu = F_{\nu,\rm peak} \times \begin{cases} \nu_c^{-1/3}\nu^{1/3} & \nu < \nu_c < \nu_m \ [A] \\ \nu_c^{1/2}\nu^{-1/2} & \nu_c < \nu < \nu_m \ [B] \\ \nu_m^{(p-1)/2}\nu_c^{1/2}\nu^{-p/2} & \nu_c < \nu_m < \nu \ [C] \end{cases} \quad (1)$$

- "Slow cooling", $\nu_m < \nu_c$:

$$F_\nu = F_{\nu,\rm peak} \times \begin{cases} \nu_m^{-1/3}\nu^{1/3} & \nu < \nu_m < \nu_c \ [D] \\ \nu_m^{(p-1)/2}\nu^{-(p-1)/2} & \nu_m < \nu < \nu_c \ [E] \\ \nu_m^{(p-1)/2}\nu_c^{1/2}\nu^{-p/2} & \nu_m < \nu_c < \nu \ [F] \end{cases} \quad (2)$$

We adopt the standard assumption that the energy dissipated by the forward shock is used both in generating the magnetic field and in accelerating the electrons.

This assumption implies that the electrons characteristic Lorentz factor is linearly proportional to the bulk Lorentz factor, $\gamma_{el} \propto \epsilon_e \Gamma$, and similarly the energy density in the magnetic field, $B^2/8\pi = \epsilon_B u$, where u is the energy density of the material behind the shock and $\epsilon_B < 1$ is the fraction of post-shock thermal energy used in generating the magnetic field. This gives $B \propto \epsilon_B^{1/2} n^{1/2} \Gamma$.

In the literature, two scenarios are in frequent use in describing the ambient density profile. The first is a constant density interstellar medium (ISM). This scenario was thoroughly considered in the literature. It is easy to show that in this scenario, during the coasting phase, the flux continuously increases in all 6 regimes [A]–[F], as the expanding flow continuously accumulates particles from the ISM which are accelerated by the forward shock and radiate.

A second scenario (also in wide use) is that in which the GRB explosion occurs into a pre-ejected stellar wind with constant mass ejection rate and constant wind velocity. These imoly that the density drops as $\rho(r) \propto r^{-2}$. As we show below, under certain conditions, during the coasting phase the obtained lightcurve is ≈flat. We therefore focus here and below on this scenario.

Using the scaling relations derived above, it is straightforward to show that during the coasting phase where $\Gamma = cosnt$, $\nu_m \propto t^{-1}$ (following the decrease in the density with radius, which leads to a decrease in the magnetic field), and $\nu_c \propto t$ from a similar reason. During the decaying self-similar expansion, $\Gamma(r) \propto r^{-1/2}$, and a similar argument gives $\nu_m \propto t^{-3/2}$ and $\nu_c \propto t^{1/2}$. We thus find that both during the coasting and during the self-similar phases in a "wind" scenario, ν_m decreases with observed time, while ν_c increases. These behaviours are demonstrated (along side the 6 regions, [A] – [F]) in Figures 1 and 2.

The most relevant regions are regions [E] and [F]. Using the scaling relations of ν_m, ν_c and $N_e \propto r$, one obtains the scaling relations for these regions:

Table 1. Scaling relations of regions [E] and [F].

Region	Coasting phase	Self-similar decay phase
F ($\nu_c < \nu$)	$F_\nu \propto t^{(2-p)/2}\nu^{-p/2} \sim t^0$	$F_\nu \propto t^{(2-3p)/4}\nu^{-p/2} \sim t^{-1}$
E ($\nu < \nu_c$)	$F_\nu \propto t^{(1-p)/2}\nu^{-(p-1)/2} \sim t^{-0.5}$	$F_\nu \propto t^{(1-3p)/4}\nu^{-(p-1)/2} \sim t^{-1.25}$

Note: [a] Sample table footnote.

These results can now be confronted with the data. In region [F], which is always the earlier due to the rise of ν_c, one finds that at early times, the expected lightcurve is flat (if the power law index of the accelerated electrons is $p = 2$), which later decays as $F_\nu(t) \propto t^{-1}$. This is indeed what is observed in many GRBs that show a plateau. This model therefore provides an excellent explanation to the observed plateau phase. We note that as the optical band transient from region [F] to region [E] earlier than the x-ray band (see Figures on p. 3145), the optical lightcurve may very well decay during the X-ray plateau.

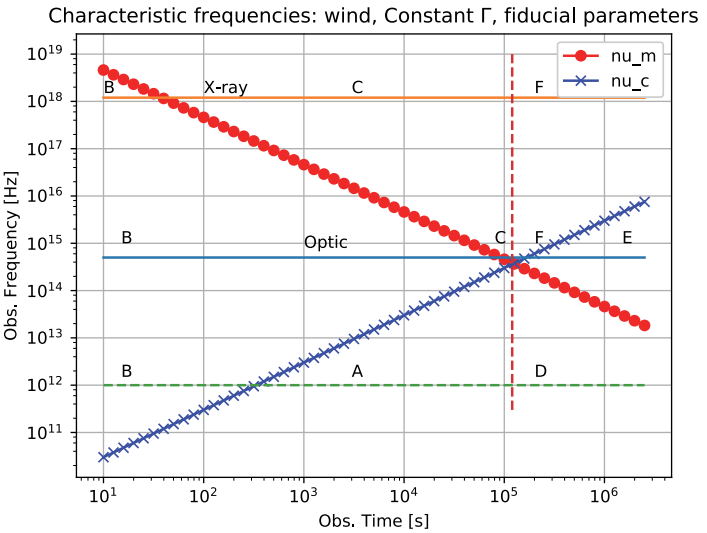

Fig. 1. Evolution of the characteristic synchrotron frequencies, ν_m and ν_c, calculated here for typical GRB parameters, during the coasting phase ($\Gamma_i = const$) for an explosion into a "wind" density environment, $\rho(r) \propto r^{-2}$. Marked are regions [A] – [F]. It is clear from the figure, that a given observed frequency change its regime in only one of two orders: Either $[B] \rightarrow [A] \rightarrow [D] \rightarrow [E]$ or $[B] \rightarrow [C] \rightarrow [F] \rightarrow [E]$.

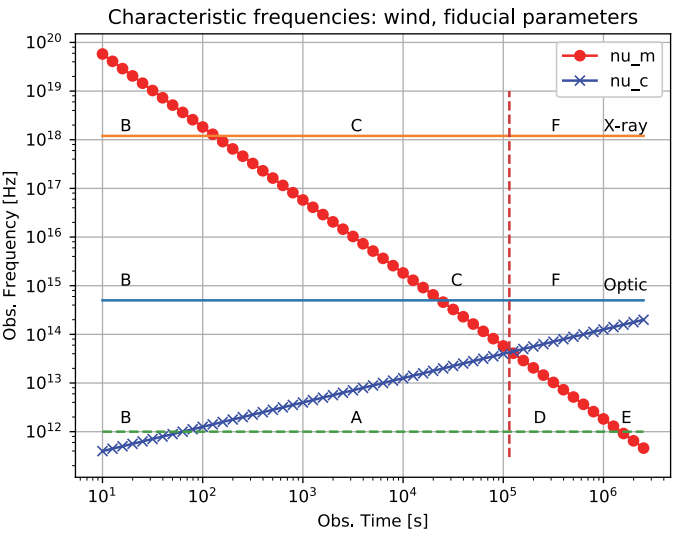

Fig. 2. Same as Figure 1, for evolution during the self-similar (decaying) expansion phase that follows the coasting phase.

4. Extracting information on the physical parameters

The excellent agreement between the theory and the data, calls for a simple interpretation according to which the transition from the plateau to the decay lightcurve marks the transition from the coasting to the self-similar expansion phases. For an explosion into a "Wind" environment, this transition time is related to the outflow parameters via

$$t^{\rm ob.}_{tran} = (1+z)\frac{9E}{32\pi A c^3 \Gamma_i^4} \tag{3}$$

where A is the proportionality constant of the wind density ($\rho(r) = Ar^{-2}$), Γ_i is the initial (coasting) Lorentz factor, E is the isotropic-equivalent energy and z is the redshift. Thus, for bursts with known redshift, the transition time provides a direct information on the value of $A\Gamma_i^4$.

Furthermore, when the lightcurve is flat, the flow is in region [F], and the parametric dependence of the x-ray flux is $\nu F_\nu(x) \propto c^3 A \Gamma_i^4 \epsilon_e d_L^{-2}$, where d_L is the luminosity distance. Thus, for bursts with known redshift (hence energy), the transition time combined with the x-ray flux provides a direct measurement on the fraction of energy given to the accelerated electrons, ϵ_e.

A decaying optical flux accompanying the flat x-ray plateau implies that the optical frequency must be in region [E]. In this case, the flux at the optical (say, R)-band is $\nu F_\nu(R) = F_{\nu,peak}\nu_m^{1/2}\nu_R^{1/2}$. For power law index $p = 2$, this gives a parametric dependence connecting $A^{7/4}\Gamma_i^3\epsilon_B^{3/4}$. This implies that for a given density (a value of A), there is a single corresponding value of the magnetization ϵ_B (as well as of the coasting Lorentz factor, Γ_i). This can be used in the opposite direction: an additional knowledge of ϵ_B, such as equipartition, or some fraction of it, can be used to determine the ambient density and the Lorentz factor.

In a recent paper [Dereli-Begue et. al., submitted] we used this method to extract information about the physical parameters of GRB outflow, as well as their initial Lorentz factor. A very interesting result, is that for the sample of GRBs with x-ray plateau, the initial Lorentz factor is typically in the range $20 \leq \Gamma_i \leq 200$, smaller than the values inferred by other methods. As explained above, there is no contradiction, and the results obtained in fact extend the known range of Lorentz factors in GRB outflows.

In this conference proceeding we summarise our investigation of a correlation discovered between the afterglow luminosity (measured at restframe 200 s; log L_{200s}) and average afterglow decay rate (measured from restframe 200 s onwards; $\alpha_{>200s}$) of long duration Gamma-ray Burst (GRB) afterglows, found in both the optical/UV and X-ray afterglows. We examine the correlation in the X-ray light curves and find that it does not depend on the presence of specific features in the X-ray light curve. We test how the optical and X-ray parameters log $L_{O,200s}$, log $L_{X,200s}$, $\alpha_{O,>200s}$, $\alpha_{X,>200s}$ relate to each other and to parameters from the prompt emission phase. Using a Monte Carlo simulation, we explore whether these relationships are consistent with predictions of a basic standard afterglow model. We conclude that most of the correlations we observe are consistent with a common underlying physical mechanism producing GRBs and their afterglows regardless of their detailed temporal behaviour, but this basic model has difficulty explaining correlations involving $\alpha_{>200s}$. We therefore briefly discuss alternative more complex afterglow models.

Keywords: Gamma-ray bursts; correlations

1. Introduction

Gamma-ray bursts (GRBs) are intense flashes of gamma-rays that are usually accompanied by an afterglow, longer lived emission that may be detected at X-ray to radio wavelengths. Studies of single GRBs provide exceptional detail on the behaviour and physical properties of individual events. However, statistical investigations of large samples of GRBs aim to find common characteristics and correlations

that link individual events and therefore provide insight into the mechanisms common to GRBs. Statistical investigations performed so far have found a number of trends and correlations within and linking the prompt gamma-ray emission and the afterglow emission e.g., Ref. 1–10.

In this conference proceeding, we focus on the discovery of a correlation, found in a sample of optical/UV afterglow light curves,[11] between the logarithmic brightness ($\log L_{O,200s}$; measured at restframe 200 s and at a restframe wavelength 1600 Å), and their average decay rate ($\alpha_{>200s}$; measured from restframe 200 s onwards with a single power-law). This correlation has also been found at X-ray wavelengths.[12] To gain insight into the origin of the luminosity-decay correlation, we investigated the X-ray sample and how it relates to other GRB properties.[12,13] Ref. 12 discovered the $\log L_{200s} - \alpha_{>200s}$ in the X-ray afterglows observed by the *Swift* X-ray Telescope (XRT[14]). Ref. 13 compared the parameters of the optical/UV $\log L_{200s} - \alpha_{>200s}$ correlation with the equivalent values from the X-ray and also explored their relationship to properties of the prompt emission, namely the isotropic energy E_{iso} and the peak energy E_{peak}. In the following, we will provide a summary of these papers.

2. Sample Selection

The X-ray light curves were retrieved from the University of Leicester *Swift*-XRT Team GRB repository.[15,16] Ref. 12 selected X-ray afterglows of *Swift*/BAT detected GRBs, that were observed between December 2004 and March 2014, that had measured redshifts, had at least 3 light curve bins and started within a factor of restframe 200 s, t_{200s}. The final sample includes 246 GRBs; 237 long and 9 short. The count rate light curves were converted to flux density at 1 keV using the spectral index from the automated fits to the photon counting mode data, and then to intrinsic luminosity. All light curve fitting is performed in the count rate domain.

The Ref. 13 sample, used to compare the properties of the X-ray, optical afterglows together with their prompt emission parameters, consists of 48 long GRBs that overlap the Ref. 11 and Ref. 12 samples. The optical/UV luminosity light curves were produced at a common wavelength of 1600 Å.[11]

To measure luminosity at 200 s, $\log L_{200s}$, for the optical/UV light curves we interpolated between 100 and 2000 s and for the X-ray we measured the luminosity at 200 s from the best-fit light curve model.[17] To obtain the average decay rate $\alpha_{>200s}$, a single power-law was fit to each optical/UV and X-ray light curve from 200 s onwards.

For some X-ray afterglows, an initial steep decay, associated with the tail of the prompt emission,[18] can contaminate the initial part of the X-ray light curve. Of the 246 X-ray light curves, the steep decay segment is found to contaminate 23 X-ray light curves at restframe 200 s. We identify a light curve segment to have a prompt origin if there is a steep to shallow transition with $\Delta\alpha > 1.0$. In these situations the average decay index is measured with a simple power-law fit to data beyond restframe 200 s and after the steep to shallow transition. In order to get a better

estimate of the afterglow luminosity at restframe 200 s, we extrapolate back to restframe 200 s the first segment of the best-fit light curve that is not contaminated by the prompt emission (see also Ref. 12).

To compare the afterglow properties with the prompt emission properties we determined the isotropic energy E_{iso} and restframe peak energy, E_{peak} from the γ-ray emission, following Ref. 17. Of the 48 GRBs that overlap the optical and X-ray samples,[11,12] we determined E_{peak} for 44 GRBs and E_{iso} for 47 GRBs.

We determine the strength of the correlation using the IDL tool *r_correlate*, which measures the Spearman rank coefficient (R_{sp}), and its corresponding null hypothesis probability (p). We also use the partial Spearman rank correlation to test the dependence of each correlation on redshift.

We perform a linear regression analysis using the IDL routines *fitexy* and *sixlin*: *fitexy* is used when both parameters have errors, *sixlin* is used when we do not know the errors on one or both parameters. Since there are only a handful of GRBs with errors on the E_{iso} and E_{peak} parameters, we choose to discard errors in both parameters and use *sixlin* when determining the strength and significance of each correlation with one of these parameters involved.

3. Results

3.1. $\log L_{X,200s} - \alpha_{X,>200s}$ *correlation*

Within the sample of 246 X-ray afterglow light curves we see evidence for a correlation between $\log L_{X,200s}$ and $\alpha_{X,>200s}$, similar to that in the optical/UV.[11] The X-ray afterglow sample consists of long and short GRBs and the light curves are often more complex than the optical/UV, consisting of features such as plateaus and flares that may add scatter or influence the correlation. We test these effects by dividing the sample by specific characteristics and reproducing the same analyses. We report all of these tests and the final correlation in Table 1 and Fig. 1.

The first test is to determine if the $\log L_{X,200s} - \alpha_{X,>200s}$ correlation is observed for both short and long GRBs. Separating GRBs in to long and short classes, we find that long GRBs are significantly correlated, but no significant correlation is found for the short GRBs. This suggests that their is some intrinsic difference in the afterglow properties of short and long GRBs, be it their environment or jet dynamics. For all further tests of the $\log L_{X,200s} - \alpha_{X,>200s}$ correlation, we exclude short GRBs.

X-ray flares have been shown to have an internal rather than external shock origin and may be a potential source of contamination in measuring the $\log L_{X,200s}$ and $\alpha_{X,>200s}$ parameters. We first separate those afterglows with X-ray flares (without removing flaring intervals) and those without flares, and find that the two samples show very similar correlation strengths and slopes, but with slightly more scatter in the sample with flares. We do not exclude GRBs with flares, instead we exclude the flaring intervals from the light curves and refit them to obtain $\log L_{X,200s}$ and

$\alpha_{\rm X,avg,>200s}$. Re-running the Spearman rank test, on the entire sample we find a tighter correlation. Henceforth, we therefore, continue our investigation using the flare-removed average decay fits.

The average decay rate may also be influenced by the plateau phase observed in some X-ray afterglows (e.g Ref. 17). For example, a light curve with an extremely long plateau (e.g. GRB 060729; Ref. 19) may have a shallower average decay, whereas GRBs without plateaus would be steeper. In addition Refs. 20, 21 have shown that there is a relationship between the time and flux of the end of the X-ray plateau, which could be another manifestation of the log $\rm L_{200s} - \alpha_{>200s}$ correlation. We thus divide the X-ray sample in to those with and without plateaus and to determine if the correlation is still present in both sub-samples. The results in Table 1 indicate that the luminosity-average decay correlation is present and similarly significant in both sub-samples. This suggests that the plateau feature is not responsible for producing the correlation and is not solely responsible for regulating the average afterglow decay.

Table 1. Linear regression and correlation statistics for each test of the X-ray light curve sample. The partial Spearman rank coefficient tests the dependence of the given set of parameters on redshift. For the regular or partial Spearman rank coefficient, the corresponding null hypothesis is given to its right. This table is adapted from Table 2 in Ref. 12.

Sample	Parameters		Spearman	Null	Partial	Null	Best fit linear regression		Number
	x-axis	y-axis	Rank	Hypothesis	Spearman Rank	Hypothesis	Slope	Constant	in Sample
Short	log $\rm L_{X,200s}$	$\alpha_{X,>200s}$	-0.07	> 0.10	0.11	> 0.10	$0.16^{+0.10}_{-0.39}$	$-3.40^{+11.16}_{-2.77}$	9
Long	log $\rm L_{X,200s}$	$\alpha_{X,>200s}$	0.59	$\ll 10^{-6}$	0.59	$\ll 10^{-6}$	$0.27^{+0.04}_{-0.04}$	$-6.99^{+1.23}_{-1.10}$	237
Flares	log $\rm L_{X,200s}$	$\alpha_{X,>200s}$	0.58	$\ll 10^{-6}$	0.56	$\ll 10^{-6}$	$0.30^{+0.07}_{-0.06}$	$-7.91^{+1.84}_{-2.17}$	134
No Flares	log $\rm L_{X,200s}$	$\alpha_{X,>200s}$	0.59	$\ll 10^{-6}$	0.64	$\ll 10^{-6}$	$0.28^{+0.03}_{-0.04}$	$-7.27^{+1.28}_{-1.01}$	103
Plateau	log $\rm L_{X,200s}$	$\alpha_{X,>200s}$	0.58	$\ll 10^{-6}$	0.55	$\ll 10^{-6}$	$0.26^{+0.05}_{-0.06}$	$-6.81^{+1.84}_{-1.43}$	156
No Plateau	log $\rm L_{X,200s}$	$\alpha_{X,>200s}$	0.57	$\ll 10^{-6}$	0.61	$\ll 10^{-6}$	$0.26^{+0.06}_{-0.05}$	$-6.82^{+1.60}_{-1.83}$	81
Final	log $\rm L_{X,200s}$	$\alpha_{X,>200s}$	0.59	$\ll 10^{-6}$	0.59	$\ll 10^{-6}$	$0.27^{+0.04}_{-0.04}$	$-6.99^{+1.23}_{-1.11}$	237

3.2. *Prompt emission and afterglow parameter comparison*

We now compare the parameters of the optical/UV and X-ray log $\rm L_{200s} - \alpha_{>200s}$ correlations using the 48 GRBs that overlap both samples. The results are given in Table 2. Using the same GRBs for the optical and X-ray log $\rm L_{200s} - \alpha_{>200s}$ correlation we find the slopes of the linear regressions are consistent at 1σ. When swapping the X-ray and optical/UV luminosity and decay parameters, i.e log $\rm L_{O,200s}$ versus $\alpha_{\rm X,>200s}$ and log $\rm L_{X,200s}$ versus $\alpha_{\rm O,>200s}$ we find similar strength relationships. Strong correlations are also observed when correlating log $\rm L_{O,200s}$ vs log $\rm L_{X,200s}$ and $\alpha_{\rm O>200s}$ vs $\alpha_{\rm X,>200s}$.

In Table 2 we also provide the results of the comparison of the parameters of the optical/UV and X-ray luminosity-decay correlations with the prompt emission parameters: log $\rm E_{iso}$ and $\rm E_{peak}$. Comparison of the optical/UV and X-ray luminosity with log $\rm E_{iso}$ indicates strong correlations and the slope of the linear regressions are consistent to within 1σ. We also provide the results of the comparison of log $\rm E_{iso}$

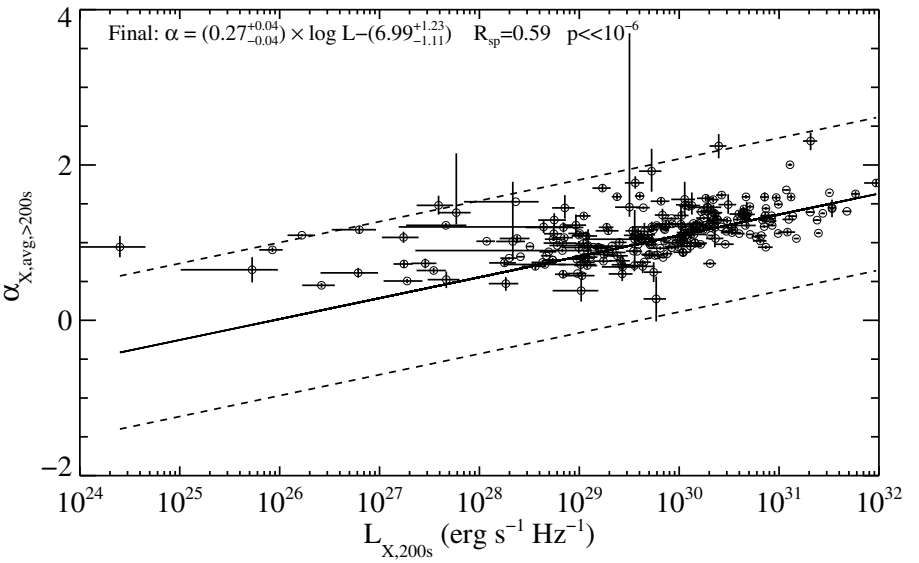

Fig. 1. Final average decay - luminosity correlation using the sample that includes flare correction and those only of long duration, with corrections and sub-sample optimisation described in §3. The solid line indicates the best fit regression, and the dashed lines indicates the 2σ deviation. This figure is reproduced from Fig. 9 of Ref. 12.

Table 2. For each pair of parameters examined, this table contains: the Spearman rank correlation coefficient with its associated null hypothesis; the coefficient of the partial Spearman rank with its associated null hypothesis; the slope and constant values provided by the best fit linear regression. We also provide the 1σ error of the Spearman rank coefficient. Table is a reproduction of Table 2 from Ref. 13.

Parameters		Spearman Rank	Null	Partial	Null	—Best fit linear regression—	
x-axis	y-axis	Coefficient	Hypothesis	Spearman Rank	Hypothesis	Slope	Constant
log $L_{O,200s}$	log $L_{X,200s}$	0.81 (0.05)	5.26×10^{-12}	0.70	2.85×10^{-8}	0.91 ± 0.22	1.04 ± 6.94
$\alpha_{O,>200s}$	$\alpha_{X,>200s}$	0.77 (0.07)	1.10×10^{-10}	0.75	1.27×10^{-9}	0.97 ± 0.10	0.25 ± 0.09
log $L_{O,200s}$	$\alpha_{O,>200s}$	0.58 (0.11)	1.90×10^{-5}	0.50	2.85×10^{-4}	0.28 ± 0.04	-7.72 ± 1.31
log $L_{X,200s}$	$\alpha_{X,>200s}$	0.69 (0.09)	8.03×10^{-8}	0.63	1.58×10^{-6}	0.26 ± 0.05	-6.71 ± 1.39
log $L_{O,200s}$	$\alpha_{X,>200s}$	0.60 (0.12)	6.87×10^{-6}	0.52	1.53×10^{-4}	0.29 ± 0.03	-8.13 ± 1.08
log $L_{X,200s}$	$\alpha_{O,>200s}$	0.65 (0.10)	5.58×10^{-7}	0.60	7.58×10^{-6}	0.32 ± 0.06	-8.70 ± 1.68
log E_{iso}	$\alpha_{O,>200s}$	0.54 (0.12)	9.05×10^{-5}	0.44	1.96×10^{-3}	0.21 ± 0.05	-10.22 ± 2.57
log E_{iso}	$\alpha_{X,>200s}$	0.57 (0.11)	3.12×10^{-5}	0.47	8.70×10^{-4}	0.21 ± 0.04	-9.60 ± 2.16
log E_{iso}	log $L_{O,200s}$	0.76 (0.06)	4.51×10^{-10}	0.66	4.59×10^{-7}	1.09 ± 0.13	-25.27 ± 6.92
log E_{iso}	log $L_{X,200s}$	0.83 (0.05)	5.04×10^{-13}	0.76	4.78×10^{-10}	1.10 ± 0.15	-27.81 ± 7.89
log E_{peak}	$\alpha_{O,>200s}$	0.45 (0.13)	2.05×10^{-3}	0.38	1.20×10^{-2}	0.48 ± 0.17	-0.22 ± 0.41
log E_{peak}	$\alpha_{X,>200s}$	0.48 (0.13)	9.22×10^{-4}	0.40	7.52×10^{-3}	0.48 ± 0.15	0.03 ± 0.36
log E_{peak}	log $L_{O\times200s}$	0.66 (0.11)	1.16×10^{-6}	0.58	3.51×10^{-5}	2.97 ± 0.76	24.53 ± 1.95
log E_{peak}	log $L_{X,200s}$	0.75 (0.10)	4.74×10^{-9}	0.70	1.38×10^{-7}	2.97 ± 0.67	22.50 ± 1.73

with $\alpha_{O,>200s}$ and $\alpha_{X,>200s}$. The Spearman rank coefficients are smaller than those found between luminosity and log E_{iso}, but do still indicate a correlation. Within 1σ the slopes of the linear regression for both the optical/UV and X-ray $\alpha_{>200s}$ versus log E_{iso} are consistent with each other. Similar results can are also found for

the four optical/UV and X-ray parameters versus E_{peak}, see Table 2. However, the relationships involving E_{peak} are weaker in comparison to the relationships observed with log E_{iso}; consistent with that found by Ref. 6.

4. Discussion

The log $L_{200s} - \alpha_{>200s}$ correlation, observed in the optical/UV and X-ray light curves, suggests that the brightest afterglows decay more quickly than the fainter afterglows. This points towards a common underlying mechanism producing the afterglow emission in the X-ray and optical/UV afterglows. We can therefore generally exclude models that invoke different emission mechanisms that would result in the log $L_{200s} - \alpha_{>200s}$ correlation being observed in only one frequency band.

Pre-*Swift* observations of late time X-ray afterglows also seemed to suggest the brightest X-ray afterglows decay more quickly than fainter afterglows,[22–24] but a larger sample including some of the first *Swift* X-ray light curves[25] was not able to support previous claims (see also Ref. 12). In this analysis, the correlation between luminosity and temporal behaviour is investigated at a much earlier time, when there is greater spread in the luminosity distribution, and the average decay index is determined using almost the entire observed afterglow.

We also have shown that the X-ray and optical/UV log L_{200s} are correlated with log E_{iso} and E_{peak}. This is consistent with previous studies (e.g. Refs. 23, 26–28), in particular Refs. 6 and 29, who performed a similar study using early X-ray luminosity, 5−10 minutes after trigger. We have also shown that the optical/UV and X-ray $\alpha_{>200s}$ are correlated with log E_{iso} and E_{peak}. Altogether, these correlations indicate that the GRBs with the brightest, fastest, decaying afterglows also have the largest observed prompt emission energies and typically larger peak spectral energy.

We now investigate if these observations are consistent with the predictions of a basic standard afterglow model; an isotropic outflow with no reverse shock or energy injection. The standard afterglow model predicts different relationships between L, α and other parameters depending on the location and ordering of the synchrotron spectral frequencies relative to the observing bands. Therefore to obtain the expected relationships between various parameters for a sample of GRBs we performed a Monte Carlo simulation. Using 10^4 trials, we simulated the optical/UV (at 1600 Å) and X-ray (at 1 keV) flux densities for 48 GRBs using equation 8 of Ref. 30 and equations 4, 5 and 6 given in Ref. 31 for $F_{\nu,max}$, ν_m and ν_c. In this simulation we assume that all GRBs are produced in a constant density medium. To compute $F_{\nu,max}$, ν_m and ν_c we needed to determine values for the microphysical parameters. These were selected at random from log-normal distributions which had 3σ intervals ranging between: 0.01-0.3 for the fraction of energy given to the electrons, ϵ_e; $5\times10^{-4}-0.5$ for the fraction of energy given to the magnetic field, ϵ_B, and $10^{-3}-10^{3}\mathrm{cm}^{-2}$ for the density of the external medium. For the electron energy index p, we centred the distribution at 2.4, as determined by Ref. 32, however, we set

the 1σ width to be 0.2 rather than 0.59. Since the closure relations fail for p values < 2, we re-selected p when $p < 2$ was selected. The value of p along with the position of ν_c relative to the observed band and redshift (selected from a uniform distribution with the range 0.5 - 4.5, a similar range as the observed sample) dictate the values of α, β and the k-correction (as given in Ref. 33).

For the 48 GRBs in each trial, we selected a prompt emission energy from a log-normal distribution with a 3σ range $10^{51} - 10^{54}$ erg; a range similar to that of the GRBs in this sample. We picked a random value between 10% and 99% for the efficiency, which we used to convert the prompt emission energy into kinetic energy. Once all the microphysical parameters, redshift and kinetic energy had been selected, we were then able to determine the position of ν_c and thus knew where it was in relation to ν_O and ν_X. With this information, we then calculated the value of the optical/UV and X-ray fluxes and converted these to luminosity. As a byproduct of calculating the optical/UV and X-ray luminosities, we also have simulated distributions for E_{iso} and α. Therefore we also produce predictions for comparisons that involve these parameters. For the parameters of 48 GRBs in each trial, we performed linear regression using the IDL routine *sixlin*, and we also calculated the Spearman rank coefficient. The results of the simulation can be found in Table 3.

Table 3. The Spearman rank coefficient and linear regression parameters as predicted by the synchrotron model for a sample of 48 GRBs. These values were computed with a Monte Carlo simulation with 10^4 trials. Table is a reproduction of Table 1 from Ref. 13.

Parameters		Simulated Spearman	—Best fit linear regression for simulation—	
x-axis	y-axis	Rank Coefficient	Slope	Constant
$\log L_{O,200s}$	$\log L_{X,200s}$	0.92 ± 0.0	0.82 ± 0.0	3.76 ± 1.25
$\alpha_{O,>200s}$	$\alpha_{X,>200s}$	0.74 ± 0.0	1.10 ± 0.1	0.04 ± 0.17
$\log L_{O,200s}$	$\alpha_{O,>200s}$	0.30 ± 0.14	0.04 ± 0.02	-0.31 ± 0.65
$\log L_{X,200s}$	$\alpha_{X,>200s}$	0.20 ± 0.14	0.04 ± 0.03	0.10 ± 0.78
$\log E_{iso}$	$\alpha_{O,>200s}$	0.06 ± 0.15	0.03 ± 0.06	-0.32 ± 2.91
$\log E_{iso}$	$\alpha_{X,>200s}$	0.09 ± 0.15	0.04 ± 0.06	-0.76 ± 3.13
$\log E_{iso}$	$\log L_{O,200s}$	0.51 ± 0.11	4.43 ± 1.03	-200.76 ± 54.10
$\log E_{iso}$	$\log L_{X,200s}$	0.54 ± 0.11	3.28 ± 0.71	-142.22 ± 37.33

In the basic standard afterglow model, the optical/UV and X-ray emission is produced by the same mechanism in an isotropic outflow, we would therefore expect to see relationships between $\log L_{O,200s}$ & $\log L_{X,200s}$ and $\alpha_{O,>200s}$ versus $\alpha_{X,>200s}$. Our observed relationships between these parameters can therefore be explained easily by the standard afterglow model and are fully consistent with the simulations. A relationship between $\log E_{iso}$ and $\log L_{200s}$ is also expected in the standard afterglow model, but the comparison of our observed relationship to the simulations suggests that the observed linear regression slope is less steep than predicted by the simulation. Furthermore, the relationships we observe, between $\log L_{200s}$ and $\alpha_{>200s}$,

and log E_{iso} and $\alpha_{>200s}$, are not expected in the standard afterglow model and are not predicted by the simulations.

Since the standard afterglow does not succeed in fully predicting all of our observed correlations, it is likely that a more complex outflow model is required. This conclusion is similar to that drawn during the separate investigation of the optical/UV log $L_{200s} - \alpha_{>200s}$ decay correlation.[11]

4.1. *Alternative Models*

There are three main possibilities that could make the outflow complex enough to be able to reproduce the observed correlations. The first is that perhaps there is some mechanism or parameter that controls the amount of energy given to and distributed during the prompt and afterglow phases and that also regulates the afterglow decay rate. This should occur in such a way that for events with the largest gamma-ray isotropic energy, the energy given to the afterglow is released quickly, resulting in an initially bright afterglow which decays rapidly. Conversely, if the gamma-ray isotropic energy is smaller, then the afterglow energy is released slowly over a longer period, the afterglow will be less bright initially and decay at a slower rate.

The second possibility is that the correlations could be a geometric effect, perhaps the result of the observer's viewing angle. Jets viewed away from the jet-axis may have fainter afterglows that decay less quickly in comparison to afterglows

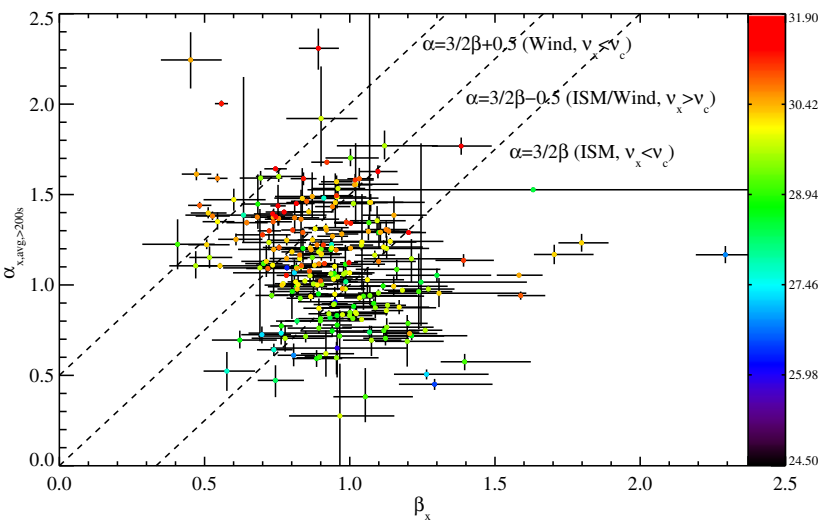

Fig. 2. The average temporal decay ($\alpha_{X,>200s}$) and average spectral energy index (β_X) are compared with log $L_{X,200s}$ (colour scale), demonstrating consistency and trends with the closure relations (dashed lines). The high luminosity (redder) points are roughly consistent with wind-like environments. This figure is reproduced from Fig. 15 of Ref. 12.

viewed closer to the centre of the jet (see Fig 3. of Ref. 4). Similarly, this will also affect the observed prompt emission, with jets viewed off-axis appearing to have lower isotropic energy and lower peak spectral energy.[34]

The third possibility could be related to the circumburst environment. The closure relations relate α and the spectral index β through different relationships depending on the ordering of the synchrotron spectral parameters and the density profile or the external medium. If the correlation is affected by the circumburst environment, we expect to see GRBs with the highest luminosities favouring a particular environment. No apparent correlation is observed in the optical/UV.[11] However in the X-ray (see Figure 2), the highest luminosity GRBs tend toward the lines demarcating the r^{-2} wind environment. The ambiguity in the $\nu_x > \nu_c$ cases prohibits us from making a strong statement on the role of circumburst environment, but it may be another possible contribution in that the initially brightest GRB afterglows may be more likely to live in wind-like environments (see also Ref. 35).

5. Conclusions

This proceeding has summarised the work presented in Refs. 12 and 13. We have shown that the correlation between luminosity (measured at restframe 200 s; log L_{200s}) and average decay rate (measured from 200 s; $\alpha_{>200s}$) is observed in the X-ray light curve sample as well as the optical/UV.[11] When we rerun the correlations with the GRBs that overlap the optical/UV and X-ray samples we find the luminosity-decay correlations are consistent. This suggests a single underlying mechanism producing the correlations in both bands and it is not dependent on their detailed temporal behaviour. We also show significant correlations between the logarithmic optical/UV and X-ray luminosity (log $L_{O,200s}$, log $L_{X,200s}$) and the optical/UV and X-ray decay indices ($\alpha_{O,>200s}$ and $\alpha_{X,>200s}$) and all four of these parameters are found to be correlated with the prompt emission parameters: isotropic energy (E_{iso}) and restframe peak spectral energy (E_{peak}). Together these correlations imply that the GRBs with the brightest afterglows in the X-ray and optical/UV bands, decay the fastest and they also have the largest observed prompt emission energies and typically larger peak spectral energy. This suggests that what happens during the prompt phase has direct implications on the afterglow.

We used a Monte Carlo simulation to examine whether the standard afterglow model is able to explain the observed correlations. Overall, observed correlations between the luminosities in both the X-ray and optical/UV bands and between the luminosities and the isotropic energy are consistent with the predictions of the simulation. However, observed relationships involving the average decay indices with either luminosity at 200 s or the isotropic γ-ray energy are not consistent with the simulation. We therefore suggest that a more complex afterglow or outflow model is required to produce all the observed correlations. This may be due to either a viewing angle effect or by some mechanism or physical property controlling the

energy release within the outflow. The environment in which the GRB exploded may also contribute to the observed correlation.

Kilonova emission observed so far: A comparison with AT2017gfo

A. Rossi

INAF - Osservatorio di Astrofisica e Scienza dello Spazio, via Piero Gobetti 93/3, 40129 Bologna, Italy

E-mail: andrea.rossi@inaf.it

AT2017gfo is the first kilonova (KN) that could be extensively monitored in time both photometrically and spectroscopically. Moreover, it is the first optical counterpart of a gravitational wave source and it is associated with the short gamma-ray burst GRB 170817A. Here I present our search for the fingerprints of AT2017gfo-like kilonova emissions in the optical/NIR light curves of 39 short GRBs with known redshift. Afterwards, I show how, for the first time, our results allow us to study separately the range of luminosity of the blue and red components of AT2017gfo-like kilonovae in short GRBs. With these results at hand, I show up to which redshift a KN can be followed up by some of the current and future observatories.

Keywords: Kilonovae; Gamma-ray bursts; Neutron stars

1. Introduction

For a long time only indirect evidence associated short Gamma-ray bursts (GRBs) to the merging of compact objects, but the simultaneous detection of the gravitational wave (GW) source GW170817[1] by aLIGO/AdVirgo[2,3] and the short Gamma-ray burst GRB 170817A[4–6] has provided the first direct evidence that at least a fraction of short GRBs is associated with the merging of two neutron stars (NSs). At the same time, the discovery of AT2017gfo, the optical counterpart of GW170817,[7] allowed us, for the first time, to follow-up spectroscopically the elusive astrophysical phenomena known as "kilonova",[8,9] i.e. a thermal emission powered by the radioactive decay of elements formed via r-process nucleosynthesis in the ejecta of the NS-NS merger e.g.,[10,11]. In particular, the observations are consistent with a kilonova characterised by a blue, rapidly decaying, component and a red, more slowly evolving one. Therefore, one can distinguish between the *blue* and *red* components, depending on whether the rest-frame effective wavelength is brighter in the optical or in the NIR, respectively.

In the following, we aim to further investigate the possible range of kilonova luminosity and identify possible new kilonova candidates, comparing the optical/NIR light curves of all short GRBs (sGRBs) with known redshift up to June 2019 with those of AT2017gfo.

2. Kilonovae known to date

Although AT2017gfo is the most outstanding and clear demonstration of the existence of kilonovae, the majority of the known kilonovae are associated to sGRBs, although often the association is not very strong. Among those, the most clear evidence was found in the optical counterparts of 6 sGRBs: 050709A,[12] 060614A,[13,14] 080503,[15,16] 130603B,[17,18] 150101B,[19] 160821B,[20–23] and 070809.[24] In addition to those, there are the magnetar-powered kilonovae identified by Gao *et al.*[16] (GRBs 050724, 070714B). Unfortunately, in the case of GRB 080503 the redshift could not be measured either via spectroscopy of the afterglow or of the host galaxy; in the case of GRB 070809 the redshift is not well defined. Recently, a new KN candidate has been found associated to GRB 200222A, although this claim is not secure.[25,26] Therefore, we define a golden sample that includes all 7 GRBs with kilonova candidates claimed in the literature that have accurate redshift.

Note that the evidence of kilonova in GRBs 050724 070714B has been found by modelling the X-rays and optical light curves with magnetar-powered KN model. These magnetar KN (MKN) are expected to be more luminous, have longer duration but also bluer than the the classical KN. It should also be noted that in all these possible kilonova identifications (but GRB 150101B), the emission was preceded by a bright GRB afterglow indicating an on-axis configuration, thus suggesting that the kilonova emission may exceed the afterglow luminosity even for on-axis GRBs.

3. Optical/NIR light curves of AT2017gfo and of short GRB afterglows

The sample of short GRBs consists of 39 objects within the redshift range $0.1 \leq z \leq 2.2$.[27] As described in,[27] to have a coverage from UV to NIR bands between $\sim$1.5 and $\sim$10.5 days after the GW trigger we built 3 early SEDs using photometric observations from the literature[7,28–34] and ten spectra of AT2017gfo[33,35] Data have been corrected for foreground Galactic extinction. In order to compare AT2017gfo with sGRB optical counterparts, we first built a set of rest-frame light curves of AT2017gfo for all the filters in which there are sGRB observations. Afterwards, we compared, in each filter, the optical and NIR luminosities of AT2017gfo with those of the sGRB counterparts in our selected sample.[27] We have distinguished between the *blue* and *red* components, depending on whether the rest-frame effective wavelength is below or above 9000 Å, respectively.

4. Possible new kilonova candidates

A kilonova is expected to show a shallow evolution close to its maximum brightness. Therefore, it can be distinguished from the standard afterglow behaviour, which has a constant power-law decay according to the standard fireball model.[36] In this context we considered a decay to be anomalously shallow when its decaying index is $\alpha < 0.75$; see also.[27] The blue component of GRB 090515 has a shallow decay

in the first 24 hours and is just $\sim$ 2 times fainter than AT2017gfo at the same time. This is also true in the case of GRB 080905A, and thus may be compatible with a kilonova with a luminosity similar to the blue counterpart of GRB 090515. However, the error of the decay index is too large ($\alpha = 0.4 \pm 1.3$) and thus we do not consider this sGRB. We also identify possible shallow decay in the cases of 150423A and 150424A which however can be interpreted otherwise. In particular, the shallow decay of GRB 150423A is too early to be compared with AT2017gfo. A more detailed analysis, which consists in modelling together the optical and X-ray light curves, is needed to further investigate the presence of kilonova emission in all cases.

5. Constraints to the kilonovae luminosity

Considering the blue component spectral band, we observe a wide range in luminosity. In particular, we can exclude the presence of an AT2017gfo-like kilonova in two cases (GRBs 050509B and 061201). Few cases with an anomalous shallow decay, namely GRBs 050724, 060614, 070714B, and 150424A, are more than 10 times brighter than AT2017gfo. Note that in the case of GRBs 150423A and 150424A the optical and X-ray light curves are very similar to those of GRB 050724 and GRB 060614, which optical re-brightening is interpreted as magnetar-powered kilonova emission by.[16] In this case, the additional source of energy would explain why they are all much brighter than AT2017gfo.

On the contrary, all the kilonovae detected in the NIR (GRBs 050709, 130603B, 160821B), are no more than 3 times brighter or fainter than AT2017gfo after 2 days. Intriguingly, there are no NIR upper limits below AT2017gfo luminosity after ~ 50 hours. In other words, in all cases when observations comparable to AT2017gfo NIR emission exist the kilonova counterpart has been detected. This suggests that all red kilonovae detected so far have similar luminosity, although we are aware that the numbers are not high enough for meaningful statistics.

6. Future perspectives

In Figure 1 I show how the peak luminosity of the blue KN changes with redshift, assuming the luminosity constraints found by[27] and summarized above. It shows that the search and follow-up of the electromagnetic (EM) counterparts will be possible during O4 and O5, like what has been done in the case GW 170817, provided hat the whole sky-map can be covered down to r$\sim$ 21 mag. Facilities like, VST, will be advantaged, but should concentrate on the smaller skymaps of tens of sq. degrees, or the regions of higher probability, to maximize the return and their gain in depth.

The Binary neutron star horizon expected for the 3rd generation of GW interferometers will extend above z=1, with the bulk of events concentrated at $z < 0.5$. Although the increment in distance translates in a huge increment in the number of GW events, including BNS and their EM counterparts, the localization will not

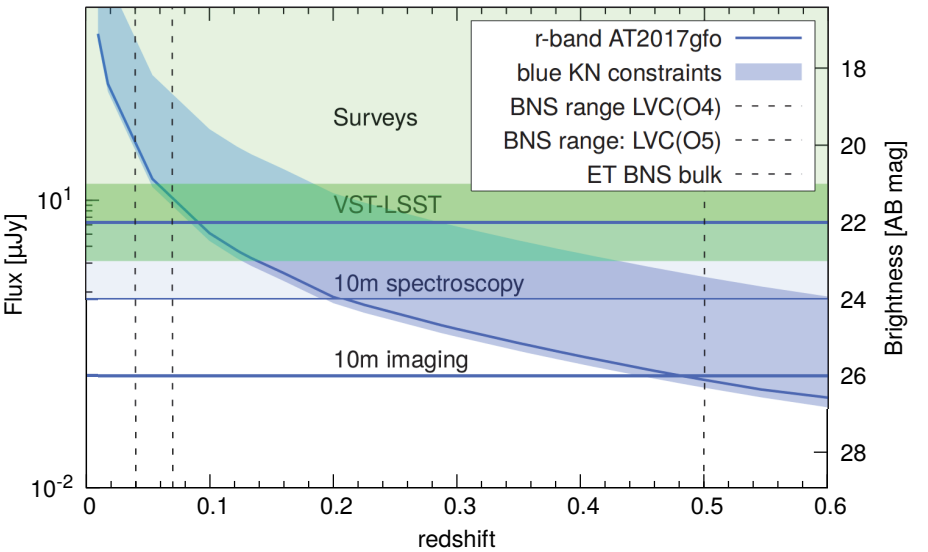

Fig. 1. Peak brightness of AT2017gfo in the r-band at different redshifts, within the constraints we derived for an AT2017gfo-like KN from the golden sample. The vertical line is the aLIGO/AVirgo detection limits for a BNS event during O4, O5 and ET. The last one is limited at $z \lesssim 0.5$ at which ET will be able to detect most of the GW signals from merging BNS. The horizontal lines are different detection limits for different class of telescopes with an exposure time of 10 min.

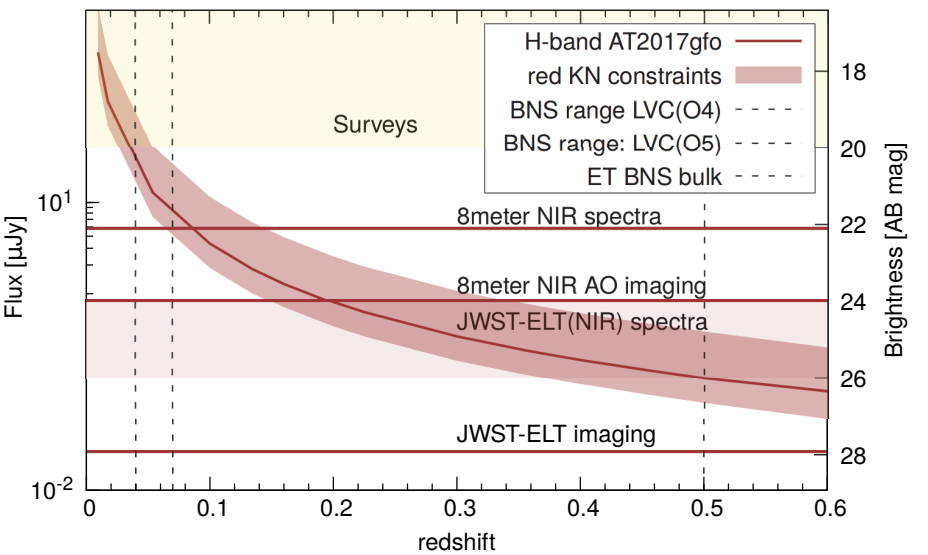

Fig. 2. The same as shown in Figure 1 but in the H-band.

improve much in respect to the present situation during LVK runs: 50% of all events will have localized with error of more than 1000 sq degrees, and only below redshift 0.2 at least 50% of events will be localized below 100 sq degrees. In this situation, what are the chances to find, follow-up and characterize the EM counterparts?

A shown in Figure 1, below redshift 0.2 the search of the EM counterpart can still be succesful thanks to the most advanced surveys if they capabilities and strategy will be adjusted to reach r 21 mags and beyond, perhaps sacrificing sky covergae to optimize depths, when this is possible. In particular, the VST telescope, or even better the Vera Rubin telescope, will be able to localize most events, or at list the brightest events. The search becomes difficult at higher redshifts, with only Vera Rubin able to successfully find the brightest events. On the contrary, once localized, the follow-up and characterization via spectroscopy will not be a problem, as the class of the 10m telescope has enough sensitivity and is well equipped for the follow-up.

More critical is the situation in the NIR, where no many facilities may be able to reach the necessary depth to successfully search and localize the EM counterpart. Still, the characterization will be guaranteed by the class of 8-10m and extremely large telescopes, together with the Nancy Roman space observatory. This situation is even more dramatic dramatic if we think that the blue kilonova is expected only if there is no prompt collapse in a black hole, and therefore the characteristic feature in common to both cases i.e., the red kilonova is the only that is always expected. One solution may be offered by a space observatory capable to detect the gama-ray signal and slew in the direction of the burst to localize its afterglow, like the current *Swift*, the future *SVOM* or the proposed *THESEUS* and *GAMOW* missions. In this case the bright afterglow can be localized up to high redshift. The only limitation is that only on-axis (or close) events will be followed up, being the emission collimated. However, it also means that all the sGRBs at $z < 0.5$ and many at $z < 1$ will be associated to a gravitational wave signal, allowing to measure both distance and redshift, constrain both masses and inclinations with implications n the cosmological studies and equation of state of the progenitor NS.

In this paper we make a prediction on the intensity and energies of neutrinos and photons coming out from the decay chain of the π-meson and μ-lepton, produced by proton-proton inelastic interaction in energetic $\left(E_{\rm iso} \gtrsim 10^{52}\ {\rm erg}\right)$ long gamma-ray bursts (Long-GRBs), within the type I binary-driven hypernova (BdHN) framework.

Keywords: Long-GRBs BdHN; *pp* interaction; GeV-TeV ν/γ

1. Introduction

In the last years multi-messenger astronomy became a fundamental technique to get complementary informations from a single cosmic source. The aim of this technique is to connect different messengers, from the same source, emerging from the same process or from a different one an which are connected spatially and temporally. The advent of new facilities able to detect high-energy astrophysical sources, as gamma-ray bursts (GRBs) or active galactic nuclei (AGN), have been/is important for the development of this field of research.

In this paper we study the neutrino and photons emission emerging from the proton–proton inelastic interaction, for the specific model of binary driven hypernova (BdHN) of long GRB. The BdHN I progenitor is a binary system composed of a carbon-oxygen star (CO_{core}) and a neutron star (NS) companion, where the CO_{core} explosion as supernova (SN) triggers an accretion process onto the NS that, for orbital periods of a few minutes, leads to the formation a black hole (BH). Close to the *cavity* formed around the BH—due to the accretion and the collapse processes—an electron–positron plasma (created in the BH formation), during its isotropic and self-accelerating expansion, it engulfs different amounts of the ejecta baryons along different directions, leading to a direction-dependent proton Lorentz factor. The protons engulfed in the ejecta along the high-density direction ($\sim 10^{23}$ particle/cm^3) reach energies in the range $1.24 \lesssim E_p \lesssim 6.14$ GeV and interact with the ejecta unshocked protons. The protons engulfed along the low density direction, instead, reach energies ~ 1 TeV and interact with the low-density (~ 1 particle/cm^3) protons of the interstellar medium (ISM). The *pp* interactions, for both the density regions, give rise to γ/ν with energies $E_{\gamma,\nu} \leq 5$ GeV and $10 \leq E_{\gamma,\nu} \leq 10^3$ GeV, respectively, for which we calculate the spectra and luminosity.

1.1. *BdHN I: from MeV to GeV and TeV neutrinos*

There are two principal classes of GRBs (see Ref. 1 for the subdivision of long and short GRBs in seven different subclasses). The "short bursts" originate in the mergers of binaries composed of a neutron star (NS) accompanied either by another NS, or a white dwarf (WD) or a black hole (BH), or mergers of binary WDs. The "long bursts" split in four different subclasses, all of them originating from binaries which have been called *binary-driven hypernovae* (BdHNe) of type I, II, III and IV.[2] In this paper, we focus only on the BdHN of type I.

The progenitors of a BdHN system could be zero-age main-sequence (ZAMS) stars ($\gtrsim 10 - 12\ M_\odot$).[3,4] The core–collapse of one of the primary and the consequent formation of a NS at it's center, leads to a system composed by this new born NS and the secondary original star. The system then evolves through mass-transfer episodes and possibly multiple common-envelope epochs.[5] These binary interactions lead to the ejection of the outermost and lighter (H/He) outermost layers of the secondary star. At this stage, the binary is composed of a CO_{core} (or a helium star) and a NS companion.[3,6,7] The different types of BdHN are distinguishable by their final state. As regards the BdHN I, the evolution of the system proceed through the

following steps. The CO_{core} explodes as SN and forms a new NS (hereafter νNS) at its center. At the same time, the ejected material triggers a hypercritical accretion process onto the NS companion. For compact binaries (orbital periods $P \sim 5$ min), the accretion onto the NS brings to the formation of a BH by gravitational collapse (see Refs. 4, 7). This final system is called BdHN I[a], and it explain energetic long bursts with isotropic energy in gamma-rays $E_{\rm iso} \gtrsim 10^{52}$ erg and peak energy $E_{p,i} \gtrsim 200$ keV. The observed occurrence rate of BdHN I ~ 1 Gpc^{-3} y^{-1}.[9]

1.1.1. *Baryonic content available for proton-proton interactions in a BdHN I*

Let's start to analyze now the structure of the baryonic matter present in the BdHN I. The three-dimensional simulations of this system,[2,7,10] pointed out that the SN ejecta, although starts expanding in a spherically symmetric way, becomes highly asymmetric by the accretion process onto the NS[7,10] and the BH formation.[11] Due to this morphology and distribution of baryonic matter around the binary component, the $e^{\pm}$–plasma created in the process of BH formation (see Refs. 12–15 for details on the creation and dynamics of the plasma), which expands isotropically from the newborn BH site, experiences a different dynamics along different directions.[16]

These studies have been specialized in the case where the $e^{\pm}$–plasma engulfs a limited amount of baryons, characterized by a *baryon load* parameter $B \lesssim 10^{-2}$. The *baryon load* is defined as $B \equiv M_b c^2/E_{e^+e^-}$, namely the ratio between the baryon rest-mass energy respect to the $e^{\pm}$ energy. Such low values of B allow the plasma to reach transparency with high Lorentz factor $\Gamma \sim 1/B \gtrsim 10^2$, needed to explain the gamma-ray prompt emission of the GRB. We denote with γ the Lorentz factor of a single particle, and with Γ the one of bulk motion.

In the direction pointing from the CO_{core} to the accreting NS, outwards and lying on the orbital plane, the NS and the BH formation cave a region characterized by very poor baryon pollution, a *cavity* (see Refs. 7, 10, 11). In the other directions along the orbital plane, the $e^{\pm}$–plasma penetrates inside the SN ejecta at $\sim 10^8$–10^{10} cm, and evolves engulfing much larger amounts of baryons, finally reaching transparency at 10^{12} cm with $\Gamma \lesssim 4$.

In order to count the baryon mass engulfed by the $e^{\pm}$–plasma, the baryon load parameter is defined as $B \equiv M_b c^2/E_{e^+e^-}$, namely the ratio between the baryon rest-mass energy respect to the e^+e^- energy. For low baryon load values ($10^{-2} - 10^{-3}$), the transparency of the $e^{\pm}$–plasma occurs for high Lorentz factor $\Gamma \sim 1/B$. For high baryon load, as we will show, the transparency is reach with $\Gamma \sim 4$.

We are ready now to set up the properties of the incident and target protons. Therefore, in BdHN I we have, at least, two types of proton–proton interactions:

(I) Interaction of the protons with low $\Gamma \sim 7$ within the self-accelerated e^+e^-p–plasma that penetrates the SN ejecta, with the unshocked protons ahead the plasma expansion front, at rest inside the ejecta.

[a] We refer the reader to Refs. 2, 8 for details on the other BdHN systems, BdHN II–IV.

(II) Interaction of the protons with $\Gamma \sim 10^2$–10^3 engulfed in the self-accelerated e^+e^-p–plasma in the direction of least baryon density around the newborn BH, with the protons at rest of the interstellar medium (ISM), at a distance $\sim 10^{16}$ cm from the system (see e.g. Ref. 17 for details).

In Sec. 2, we consider the interaction in the high density region (interaction (I) above) and describe the processes connected with the interaction along this direction. In Sec. 3, we study the interaction occurring along the low density region (interaction (II) above). Since the energy range of the interacting and produced particles are different in the two regions, also the models and the approaches used to study the interaction and get the final results differs. Finally, in Sec. 4 we summarize the main results of this work.

2. *pp* interactions inside the high-density ejecta

In this section, we analyze the *pp* interaction occurring when the $e^+e^-\gamma$–plasma starts to expands along the high-density direction and to engulf the protons present in the SN ejecta, forming a $e^+e^-\gamma p$–plasma. Consequently these protons are accelerated and interact inelastically with the target protons ahead of them, still at rest. If the the kinematic energy threshold for the production of the resonance Δ^{++} is reached, the products of the scattering are: photons (from the decay of the π^0), two ν_μ and one ν_e—considering also their antiparticle—(from the decay of $\pi^\pm$ and, consequently, of the secondary created $\mu^\pm$).

In order to study this evolution of the system, we have performed relativistic hydrodynamic (RHD) simulations—performed with a one-dimensional implementation of the RHD module of the `PLUTO` code[18]—of the $e^\pm$–plasma dynamics inside the SN ejecta (see Ref. 16,19 for additional details), described by a system of partial differential equations in only radius and time coordinates. The simulation starts at the moment of BH formation, with initial conditions taken from the final configuration of the numerical simulations in Ref. 7:

(i) The SN remnant is obtained from the explosion of the $\mathrm{CO_{core}}$ of mass $M_{\mathrm{CO}} = 11.15\ M_\odot$ evolved from a ZAMS star of $30\,M_\odot$. M_{CO} is composed by $2\ M_\odot$ for the mass of the νNS (collapsed iron core) and $9.15\,M_\odot$ conform the total ejecta mass (envelope mass).
(ii) The orbital period is $P \approx 5$ min, i.e. a binary separation $a \approx 1.5 \times 10^{10}$ cm.
(iii) The ejecta have negligible pressure, is considered to be in homologous expansion ($v(r) \propto r$) and at rest as seen from the expanding plasma.
(iv) The baryon load of the $e^\pm$–plasma is not isotropic since the baryon density is different along different directions. The density profile of the ejecta, at the BH formation time, decays with distance as a power-law, i.e. $\rho \propto (R_0 - r)^\alpha$ (see Ref. 7).
(v) The total isotropic energy of the $e^\pm$–plasma is set to $E_{e^+e^-} = 3.16 \times 10^{53}$ erg. This implies, according to the above ejecta properties, a baryon load parameter of $B = 51.75$.

The evolution from these initial conditions leads to the formation of a shock and to its subsequent expansion until reaching the outermost part of the SN.

We consider a protons energy distribution in the laboratory frame as a monochromatic function $J_p(E_p) \propto \delta(E_p - E_p^0)$ since, in the comoving frame, it can be represented by Maxwell–Boltzmann distribution. As one can guess from the energy conservation, the protons energy decrease very fast. Then we concentrate on the first stages of the expansion $\left(10^8 \lesssim r \lesssim 10^{10}\ \mathrm{cm}\right)$.

From the RHD simulations described above, we have extracted the quantities necessary for our calculations of the γ/ν spectra, namely the protons Lorentz factor at the shock front, γ_p, their energy, their density, n_{sh}, and the density of the unshocked protons, n_t.

In order to get these quantities, we have built a process that use the pressure inside the plasma, the protons Lorentz factor at the front and the protons mean–free–path λ_p to recognize the plasma front position and the possible interaction protons (above and below the front position).

From this procedure we got that the protons energy varies between the range $1.24 \leq E_p \leq 6.14$ GeV, which is high enough to produce secondary particles. The proton energy threshold to produce pions in the final state is, for the interaction $pp \to pn\pi^+$, $E_{p,\mathrm{Th}} = 1228$ MeV and, for $pp \to pp\pi^0$, $E_{p,\mathrm{Th}} = 1217$ MeV.

In the region of the expansion of the shock, at every radius, the average number density of the target protons $\langle n_t \rangle$ in the remnant varies in the range $5 \times 10^{23}\ \mathrm{cm}^{-3} \lesssim n_t \lesssim 8 \times 10^{23}\ \mathrm{cm}^{-3}$ (the higher value occurs in the beginning of the simulation, namely at the beginning of the expansion). The protons number density at the front of the expanding shell, $\langle n_{\mathrm{sh}} \rangle$, does not vary much either; it is in the range $(0.5\text{–}9) \times 10^{25}\ \mathrm{cm}^{-3}$ (the maximum value occurs in the region close to the initial radius of the expansion).

2.1. *Particles spectra*

We turn now to the describe how we have calculated the spectrum of the particles emerging form the π/μ decay[b]. For our low energy protons, the differential pp cross-section, $d\sigma(E_\pi, E_p)/dE_\pi$, is given in Ref. 20. We notice that the cross-section is different for the three types of pions $\pi^+,\ \pi^-,\ \pi^0$. The pions production rate can be computed as

$$Q_\pi(E_\pi) = cn_t \int_{E_\pi}^{E_p^{\max}} J_p(E_p) \frac{d\sigma(E_\pi, E_p)}{dE_\pi} dE_p, \tag{1}$$

with $J_p(E_p)$ the monochromatic protons energy distribution, n_t the number density of the target protons.

[b]See Ref. 19 for more details on the calculations and for the plot of the particles spectra.

We denote with $\Phi_a = dN_a/dE_a$ the spectrum of the particle a, with N_a the particle number density per unit time[c].

The spectrum of photons emerging from π^0 decay is given by

$$\Phi_{\pi^0\to\gamma\gamma}\left(E_\gamma\right) = 2\int_{E^{\min}(E_\gamma)}^{E_\pi^{\max}} \frac{Q_\pi(E_\pi)}{\sqrt{E_\pi^2 - m_\pi^2 c^4}} dE_\pi, \tag{2}$$

where $E^{\min}\left(E_\gamma\right) = E_\gamma + m_{\pi^0}^2 c^4/(4E_\gamma)$ can be derived by the kinematics of the process and the factor 2 takes into account the two produced photons.

The spectrum of $\nu_{\mu^{(1)}}$ is similarly given by

$$\Phi_{\pi\to\mu\nu_\mu}\left(E_{\nu_\mu}\right) = \frac{1}{\lambda}\int_{E^{\min}\left(E_{\nu_\mu}\right)}^{E_\pi^{\max}} \frac{Q_\pi(E_\pi)\theta\left(\lambda - \frac{E_{\nu_\mu}}{E_\pi}\right)}{\sqrt{E_\pi^2 - m_\pi^2 c^4}} dE_\pi, \tag{3}$$

where $E^{\min}\left(E_{\nu_\mu}\right) = E_{\nu_\mu}/\lambda + (\lambda/4)\left(m_\pi^2 c^4/E_{\nu_\mu}\right)$; $\lambda = 1 - r_\pi$, with $r_\pi = (m_\mu/m_\pi)^2$, is the maximum energy fraction that the neutrino emerging from the direct decay can take from the pion. The value $E_\pi^{\max}$ is calculated from the kinematics and results to be:

$$E_\pi^{\max}\left(E_p\right) = \gamma_{\rm CM}\left(E_p\right)\left[E_\pi^{\rm CM}\left(E_p\right) + \beta_{\rm CM}\left(E_p\right) p_f^{\rm CM}\left(E_p\right)\right], \tag{4}$$

where CM indicate that the Lorentz factor, the momentum and the velocity are calculated in centre-of-mass frame.

Instead, the spectrum of the $\nu_{\mu^{(2)}}$ are given by:

$$\Phi_{\pi\to\mu\to\nu_\mu/\nu_e}\left(E_\nu\right) = \int_{E^{\min}(E_\nu)}^{E_\pi^{\max}} \frac{Q_\pi(E_\pi)}{\sqrt{E_\pi^2 - m_\pi^2 c^4}}\, g\left(\frac{E_\nu}{E_\pi}\right) dE_\pi, \tag{5}$$

where the functions $g(z)$ are derived in Ref. 21 and represent the ν spectra after the decay chain $\pi \to \mu \to \nu$.

The function $g(z)$ can be decomposed as the sum of an unpolarized spectrum, $g^0(z)$, plus a polarized one, $g^{\rm pol}(z)$ (see Appendix in Ref. 21). We have used the formula for the relativistic limits (given in that paper), $\beta_\pi \to 1$, which is well satisfied since the pions Lorentz factor assumes values $4.5 \leq \gamma_\pi \leq 34.5$. We have calculated the spectrum for both unpolarized and polarized case (see Ref. 19).

Altogether, the spectra of the different particles varies between values $10^{23} \leq E^2 dN_a/dE \leq 10^{31}$ erg/cm^3/s at energies $0.3 \leq E_a \leq 5$ GeV.

At this point, we can calculate the particle emissivity at every radius, ϵ_a^i, integrating over the energy of the particle a (from 0.3 to $E_\pi^{\max}$) its spectrum times E_a and, then, integrate ϵ_a^i over the volume V_i to get the total luminosity L_a. The interacting volume at the radius i is calculated as $V_i = 4\,\pi\, r_i^2\, \lambda_i$, where λ_i is the mean-free path of the protons of energy E_p^i in the shell front. Finally, the total

[c]Henceforth we denote as $\nu_{\mu^{(1)}}$ the muonic neutrino/antineutrino from the direct pion decay, $\pi \to \mu\nu_\mu$, and $\nu_{\mu^{(2)}}$ the neutrino/antineutrino from the consequent muon decay, $\mu \to e\nu_\mu\nu_e$.

energy emitted for each particle a, is given integrating L_a over the entire emission time, namely (Δt_i, is the time the shell spends to cover the distance between r_{i-1} and r_i with the velocity β_i, $\Delta t_i \approx \Delta r_i/(c\,\beta_i)$):

$$\mathcal{E}_a \approx \sum_{i=2}^{n} L_a^i \times \Delta t_i = \sum_{i=2}^{n} L_a^i \times \frac{\Delta r_i}{c\beta_i}, \tag{6}$$

The total energy emitted in photons is $\sim 4 \times 10^{52}$ erg, while the different types of ν it varies between 0.5 and 3.5×10^{51} erg. Summing all the energy emitted for all the particle, we obtain a total energy release of 9.11×10^{51} erg, that is $\approx 2.9\%$ of the energy of initial energy of the $\gamma e^{\pm}$–plasma.

3. TeV protons interacting with the ISM

In this section, we now consider the interaction of incident protons engulfed by the $\gamma e^{\pm}$–plasma in the direction of the circumburst medium (CBM) with low baryon load—we assume here $B = 10^{-3}$—with target protons of the ISM. The interaction with the ISM—located at a distance between $10^{16} \leq r \leq 10^{17}$ cm from the BH site—occurs in a spherical shell. Thus in this case, the number density of the target is $n_{\rm ISM} \sim 1$ cm^{-3} and the transparency is reached far away from the BH site, with ultra-relativistic Lorentz factor of up to $\gamma_p = \Gamma \sim 10^3$. Therefore, we adopt here that the incident protons have energies ~ 1 TeV.

The number of engulfed protons, N_p, is given by the ration between the isotropic energy of the $e^{\pm}$ times the baryon load over the protons mass. For $E_{e^+e^-} \sim 10^{53}$ erg and $B = 10^{-3}$, $N_p = 6.65 \times 10^{52}$.

Since the energy range differs from the previous case, for the computation of the particles spectrum here we have used the results obtained in Ref. 22, where a parameterization of the pp cross-section for high-energy protons and an analytic formula for the spectrum of the emerging particles is derived.

Following Ref. 22 and denoting $J_p(E_p)$ the protons energy distribution—in units cm^{-3} TeV^{-1}—in this case the production rate for the secondary particle a, $\Phi_a(E_a) \equiv dN_a/dE_a$ (for $E_p \geq 0.1$ TeV) is given by

$$\Phi_a(E_a) = c\,n_p \int_{E_a}^{\infty} \sigma_{\rm inel}^{pp}(E_p) J_p(E_p) F_a\,(x, E_p)\,\frac{dE_p}{E_p}, \tag{7}$$

with n_p the target protons density (we assume it is 1 particles/cm^3), $\sigma_{\rm inel}^{pp}(E_p)$ is the inelastic pp cross-section, $x \equiv E_a/E_p$ and F_a is the specific spectrum for the particle a derived in Ref. 22.[d]

[d]We notice that in Ref. 22 they do not distinguish between π^+ and π^-, as well as between ν and $\bar{\nu}$. So, differently from the low density/energy case, here we do not distinguish between ν and $\bar{\nu}$ too.

3.0.1. *Particles spectra*

Here the protons energy distribution is $J_p\left(E_p\right) = A\delta\left(E_p - E_p^0\right)$, with $E_p^0 = 1$ TeV and $A = N_p/V$, with N_p the number of interacting protons over the volume $V = 4\pi\left(r_2^3 - r_1^3\right)/3$, with $r_1 = 10^{16}$ cm and $r_2 = 10^{17}$ cm.

The total emitted energy for each particle a here is calculated as

$$\mathcal{E}_{tot,\ a} = \Delta t \sum_i \epsilon_a^i \times \Delta V_i = \ \epsilon_a\ \Delta t\ \Delta V, \tag{8}$$

where $\Delta V_i = 4/3\,\pi\left(r_i^3 - r_{i-1}^3\right)$, with $r_i = r_{i-1} + \delta s$—δs is the space covered by the protons with their velocities in one second.[e]

The luminosity is given by $L_a = \epsilon_a \times \Delta V_{\text{last shell}}$, where: ϵ_a the emissivity of the particle a calculated by Eq. (7), $\Delta V_{\text{last shell}} = 4/3\,\pi\left(r_2^3 - r_*^3\right)$ and $r_* = 10^{17} - \delta s$ cm and $r_2 = 10^{17}$ cm. $r_2 - r_*$ represents the last ISM shell where the accelerated protons interact—the protons spends $\Delta t = \Delta r/c\,\beta = \ 3 \times 10^6$ seconds to cross the entire ISM region and, then, it is useless to talk about total luminosity.

Then, the emissivity of all the secondary emerging particles from the *pp* interaction are given by substituting the $F_a\left(x, E_p\right)$ functions derived in Ref. 22 inside Eq. (7). We got the following results for: the total energy $\mathcal{E}_a$ emitted through all emitting region (calculated via Eq. (8)), the luminosity of the last emitting shell L_a and the particle energy for which we have the maximum value of the spectrum $E^2 dN_\gamma/dE$, $E_a^{\max}$:

(1) for photons: $\mathcal{E}_\gamma = 5.41 \times 10^{43}$ erg, $L_\gamma = 1.01 \times 10^{43}$ erg s^{-1} and $E_\gamma^{\max} = 91.62$ GeV;
(2) for muonic neutrino from direct pion decay $\left(\nu_{\mu^{(1)}}\right)$: $\mathcal{E}_{\nu_{\mu^{(1)}}} = 1.60 \times 10^{43}$ erg, $L_{\nu_{\mu^{(1)}}} = 3.01 \times 10^{42}$ erg s^{-1} and $E_{\nu_{\mu^{(1)}}}^{\max} = 44.72$ GeV;
(3) for muonic neutrino from muon decay $\left(\nu_{\mu^{(2)}}\right)$: $\mathcal{E}_{\nu_{\mu^{(2)}}} = 1.98 \times 10^{43}$ erg, $L_{\nu_{\mu^{(2)}}} = 3.71 \times 10^{42}$ erg s^{-1} and $E_{\nu_{\mu^{(2)}}}^{\max} = 63.9$ GeV.

From these results we deduce that the principal differences between the interactions considered in Sec. 2 and Sec. 3 resides in the density of the target particles in both interaction regions. Another, but less efficient, factor that has influence on the obtained results is the difference in the interacting protons energy, which is reflected onto the *pp* cross-section.

4. Summary, discussion and conclusions

In this work we have computed the photon and neutrino production via proton-proton interactions occurring within the BdHNe I scenario for energetic long GRBs, which we have recalled in Sec. 1. From the dynamics of the BdHN I formation process leads to a highly asymmetric SN ejecta around the newborn BH site. Therefore,

[e]Note that ϵ_a^i does not depend on the radius, $\epsilon_a^i = \epsilon_a$, and then $\Delta V = 4/3\,\pi\left(r_2^3 - r_1^3\right)$.

the $e^{\pm}$–plasma created in the BH formation process, during its isotropic expansion and self-acceleration, engulfs different amounts of matter of the surrounding SN ejecta, depending on the direction. Consequently, either the observation of the emitted particles are direction dependent.

In Sec. 2 we have studied the *pp* interaction along the high-density direction inside the SN ejecta. The secondary particles production occurs in the first ~ 1.5 s of the plasma expansion inside the ejecta. The $e^{\pm}$–plasma starts to expand inside the SN ejecta, engulfing protons and accelerating them to energies of a few GeV. For these low energetic protons, we adopted the cross-section given in Ref. 20. At later times, the energy of the protons is below the threshold for the production of secondary particles by *pp* inelastic scattering. The obtained results tell us that the neutrinos and photons have energies $E_{\nu_{\mu^{(1)}}} \leq 2$ GeV and E_{γ}, $E_{\nu_{\mu^{(2)}}}$, $E_{\nu_e} < 5$ GeV, with associated total energy (integrated over the whole emitting region) of $\sim 10^{50}$–10^{51} erg.

In the second part, Sec. 3, we have studied the expansion of the plasma along the direction of low baryon load $\left(B = 10^{-3}\right)$ (see, e.g., Refs. 1,23). Here, the expansion of the $\gamma e^{\pm}$–plasma along the low-density directions allows a self-acceleration of it that brings the engulfed protons to energies of up to $E_p \sim 1$ TeV ($\gamma_p \sim 10^3$). For these higher energetic protons we have followed the approach presented in Ref. 22, where the *pp* cross-section and the spectra of the emerging particles are parametrized. In this case, the secondary particles have energies $1 \leq E_a \leq 10^3$ GeV and the total emitted energy is $\sim 10^{43}$ erg.

We found also that the spectrum of the emerging particles follow approximately a cutoff power-law function (CPL) $f(E) \propto E^{\alpha} \exp E/E_c$, with spectral index $1 \leq \alpha < 3$, depending on the considered particle and the interaction region. The power-law term usually derives from the spectral index of the primary interacting protons (see, for example, Ref. 24), but since we considered a spherical expansion of the $\gamma e^{\pm} B$–plasma, and a monochromatic protons energy distribution (at each radius of the expansion), we deduce that the power-law term is intrinsic in the considered process. Instead, the exponential decay is explained by the kinematic of the process. Indeed a fraction of the parent proton energy is taken by the pion; for the direct pion decay, the $\nu_{\mu^{(1)}}$ can take, at maximum, a fraction λ of the pion energy, while the muon can take, at maximum, the entire pion energy.

Now we try to give some numbers concerning the ν detection with Earth Detectors. In general, since GRB occur at cosmological distances and this makes neutrino detection very challenging because of the very low neutrino flux arriving to the Earth.

We can obtain order-of-magnitude estimate of the probability of detection of these neutrinos considering three detectors: SuperKamiokande (SK), Hyper-Kamiokande (HK) and IceCube (IC), calculating the detection horizon.[f] The

[f]For this purpose, we use the best experimental conditions, i.e. the peak neutrino luminosity and the corresponding neutrino energy.

number of neutrinos per-unit-time and per-unit-area that arrive to the detector is

$$\frac{d^2N_\nu}{dSdt} = \frac{\mathcal{E}_\nu}{4\pi D^2 E_\nu^*}, \tag{9}$$

where $\mathcal{E}_\nu$ is the total energy emitted during 1 s in neutrinos of energy E_ν, D is the luminosity distance to the source, $E_\nu^* = E_\nu/(1+z)$ is the redshifted neutrino energy, and z the source cosmological redshift.

The number of detectable neutrino, $N_\nu^{\rm det}$, is calculated as the number of neutrino per unit of time and area that arrives to the detector, given by Eq. (9), times the cross-section for the neutrino-nucleon interaction, $\sigma_{\nu N}$ (see, e.g. Ref. 25, 26), times the number of probable interacting baryon in the detector $N_b^{\rm det} = N_A \times M_{\rm int}$—where N_A is the Avogadro number and $M_{\rm int}$ the interacting mass inside the detector—times the integration time of the detector $T_{\rm int}$, that we set to 1 second (in agreement with the time-interval of the emission inside the ejecta):

$$N_\nu^{\rm det} = \frac{d^2N_\nu}{dSdt} \times T_{\rm int} \times \sigma_{\nu N} \times N_b^{\rm det}, \tag{10}$$

For the three considered detectors is $N_b^{\rm det} = N_A \times (22.5\,{\rm kton}) = 1.35 \times 10^{34}$ baryons (for SK); $N_b^{\rm det} = (560\ {\rm kton}) \times N_A = 3.37 \times 10^{35}$ baryons (for HK); for the *Deep Core Detector* of IC, the effective volume is a function of the neutrino energy: $N_b^{\rm det} = (10\ {\rm Mton}) \times N_A = 6.022. \times 10^{36}$ baryons; $N_b^{\rm det} = (20\ {\rm Mton}) \times N_A = 1.2044 \times 10^{37}$ baryons; $N_b^{\rm det} = (30\ {\rm Mton}) \times N_A = 1.8066 \times 10^{37}$ baryons.

Now, using the relations and estimates above and considering the Hubble-Lemaître law, $c\,z = H_0 D_h$ (with $H_0 = 72$ km s^{-1} Mpc^{-1}), we can obtain the neutrino-detection horizon, D_h, i.e. the luminosity distance to the source for which we have $N_\nu^{\rm det} = 1$:

$$D_h = \frac{K H_0}{2c} + \frac{1}{2}\sqrt{\frac{K^2 H_0^2}{c^2} + 4K}, \tag{11}$$

where $K = \mathcal{E}_\nu \sigma_{\nu N} T_{\rm int} N_b^{\rm det}/(12\pi E_\nu)$.

For the low energy neutrinos ($E_\nu \leq 2$ GeV, at the production site, i.e. in the source frame) there are additional considerations that decrease the probability to detect these neutrino, namely: 1) the fact that the energy need to be divided for the factor $1+z$ and that for low energetic ν the cross-section for $\nu - N$ interaction is very low—$\sim 10^{-39}$ cm^2 (see, for example, Ref. 25, 26); 2) for these low energies, there is much background noise by atmospheric neutrinos, created in the atmospheric showers by cosmic rays and solar neutrinos.

The high energetic neutrinos ($E_\nu \leq 10^3$ GeV) from the low-density region could be, in principle, more easily detected than the previous case since at these energies there is no background noise from atmospheric and solar neutrinos and the cross-section assumes higher values $\sigma_{\nu N} \sim 10^{-37}$ cm^2.

The calculations of the horizon distance through Eq. (11) give the following results that

(I) for the ν from the high density region, $0.2 \leq D_h \leq 11.12$ Mpc;
(II) for the ν from the low density region, $22 \leq D_h \leq 954$ pc.

In both cases, we obtained the higher values with the Deep Core of the IC detector, while the lower ones are for the SK detector. This analysis suggests that only the IceCube detector might detect the neutrinos here analyzed, i.e. neutrinos produced by *pp* interactions in the context of BdHNe I, especially the one coming from the high-density region, even if all of them have the right energy range of sensibility to detect our neutrinos.

It is generally believed that General Relativity (GR) is of secondary importance in the explosion of core-collapse supernovae (CCSN). However, as 3D simulations are becoming more and more detailed, GR effects can be strong enough to change the hydrodynamics of the supernova and affect the explosion. Since a 3D simulation in full GR is computationally extremely challenging, it is valuable to modify simulations in a spherically symmetric spacetime to incorporate 3D effects. This permits exploration of the parameter dependence of CCSN with a minimum of computational resources. In this proceedings contribution we report on the formulation and implementation of general relativistic neutrino-driven turbulent convection in the spherically symmetric code `GR1D`. This is based upon *STIR*, a recently proposed Newtonian model based on mixing length theory. When the parameters of this model are calibrated to 3D simulations, we find that our GR formulation significantly alters the correspondence between progenitor mass and explosion vs. black-hole formation. We therefore believe that, going forward, simulating CCSNe in full GR is of primary importance.

Keywords: Supernovae - Simulations - Mixing Length Theory - General Relativistic Hydrodynamics

1. Introduction

This proceedings contribution is based on work published in Ref. [1]. Core-collapse supernovae (CCSNe) have been at the core of cutting-edge computational research for more than 50 years. Despite that, the details of the mechanisms driving the explosion still remain unknown, even though significant progress has been made since the first attempts at explaining CCSNe.[2–4]

Historically, one-dimensional (1D) spherically symmetric simulations were able to assess the crucial role of neutrinos in aiding the expansion of the shock through the so-called delayed neutrino-heating mechanism.[5,6] Two-dimensional (2D) simulations[7,8] and three-dimensional (3D) simulations,[9] have been only recently accessible thanks to the fast technological improvements of the last three decades.

Spherically symmetric simulations, however, have unfortunately, not led to self-consistent explosions of Fe-core CCSNe (which are the most common) since they involve all stars with masses > 11 $M_\odot$. On the other hand, there have been several simulations in 2D and 3D that have led to successful explosions.[10–16] However, 2D simulations have been recently shown[17] to favor explosions by an artificial enhancement of neutrino-heating behind the shock via an inverse turbulence cascade which is not present in 3D. Therefore, only 3D simulations can provide the final explanation as to what causes the explosion. However, despite the technological improvements of the last few decades, 3D simulations continue to present a difficult computational challenge, even for modern supercomputers.

In comparison, modern 1D simulations are significantly faster to run and are also more consistent across different codes.[18] In other words, when the initial conditions are the same, different groups obtain similar results. This guarantees a somewhat solid foundation, making 1D simulations an ideal tool to study how different input physics can affect the explosion of supernovae. To do that, first one needs to artificially trigger an explosion. In a recent paper Couch et al.[19] (hereafter CWO20) developed *STIR* (Simulated Turbulence In Reduced-dimensionality), a parametric model based upon Mixing Length Theory (MLT) that incorporates the effects of 3D turbulence in spherically symmetric simulations.

The simulations from CWO20 use Newtonian hydrodynamics and only partially include general relativistic effects through a General Relativistic Effective Potential (GREP) from Ref. [20], which is a common practice in the supernova community. However, we know that General Relativity (GR) plays an important role in the explosion of supernovae.[10,21] Hence, simulations in full GR are desirable, and in this proceedings contribution we summarize the extension of the *STIR* model to a general relativistic treatment.[1] Throughout the manuscript, we adopt natural units, i.e. $G = c = M_\odot = 1$.

2. Methods

2.1. *The STIR model of Couch et al. (2020)*

A detailed description of STIR can be found in Refs. 22, 23 and CWO20. There, it is shown that the effects of turbulence can be treated as a perturbation on the background fluid. After a Reynolds decomposition of the compressible Euler equations, and several other approximations valid in typical supernova thermodynamic environments, one arrives to the following equation describing the evolution of the turbulent kinetic energy:

$$\begin{aligned} \frac{\partial \rho v_{\rm turb}^2}{\partial t} + \frac{1}{r^2}\frac{\partial}{\partial r}[r^2(\rho v_{\rm turb}^2 v_r - \rho D_K \nabla v_{\rm turb}^2)] \\ = -\rho v_{\rm turb}^2 \frac{\partial v_r}{\partial r} + \rho v_{\rm turb}\omega_{\rm BV}^2 \Lambda_{\rm mix} - \rho \frac{v_{\rm turb}^3}{\Lambda_{\rm mix}} \quad , \end{aligned} \tag{1}$$

where

$$\Lambda_{\rm mix} = \alpha_{\rm MLT} \frac{P}{\rho g}, \tag{2}$$

$$\omega_{\rm BV}^2 = g_{\rm eff} \left(\frac{1}{\rho} \frac{\partial \rho}{\partial r} - \frac{1}{\rho c_s^2} \frac{\partial P}{\partial r} \right). \tag{3}$$

In the above equations, ρ is the mass density, v_r is the radial velocity, $\Lambda_{\rm mix}$ is the mixing length, $\omega_{\rm BV}$ is the Brunt-Väisälä frequency, c_s is the sound speed, D_K is a diffusion coefficient due to turbulence and $g_{\rm eff}$ is the magnitude of the local effective acceleration. For a fluid in hydrostatic equilibrium, $g_{\rm eff}$ simply reduces to the local gravitational acceleration g. More generally, however, in the rest frame one should take the acceleration of the fluid into account. Therefore, the total acceleration $g_{\rm eff}$ can be expressed as:

$$g_{\rm eff} = g - v_r \frac{\partial v_r}{\partial r} \ , \tag{4}$$

as described in CWO20.

The mixing length $\Lambda_{\rm mix}$ is the average distance that a convective element will travel before being mixed with (and increasing the internal energy of) the surrounding material. The Brunt-Väisälä frequency $\omega_{\rm BV}$ is the rate at which the convective elements are rising. As one can notice from Eq. (3), $\omega_{\rm BV}^2$ can be either positive or negative: when $\omega_{\rm BV}^2 > 0$ the fluid is convectively unstable, i.e. convection is generated; when $\omega_{\rm BV}^2 < 0$ the fluid is convectively stable, i.e. convection is damped. Ultimately, the main parameter of the model is $\alpha_{\rm MLT}$, which scales the mixing length to the pressure scale height in Eq. (2). Typically $\alpha_{\rm MLT} \sim O(1)$.

The diffusion coefficient D_K is defined as:

$$D_K = \alpha_K v_{\rm turb} \Lambda_{\rm mix} \ . \tag{5}$$

Similar terms appear in the internal energy, electron fraction, and neutrino energy density evolution equations (for the complete set of hydrodynamic equations used in the model, (see Eqs. 25-29 and 33 in CWO20). Therefore, strictly speaking, *STIR* has 4 additional free parameters: α_K, α_e, $\alpha_{\rm Ye}$, α_ν. However, the convective motions are not very sensitive to the value of these parameters, so we set them to 1/6 for simplicity, consistent with the choices of Ref. [24] and CWO20.

In the next section we describe a general relativistic version of the model described above.

2.2. *STIR in General relativity*

The first attempts to create a general relativistic model for convection date back to Ref. [25]. We follow the same approach, but using a slightly different formalism.

All the simulations described here[1] were run with the open-source, spherically symmetric, general relativistic code `GR1D`.[26] The Boltzmann equation for neutrino

transport is solved using an M1-scheme, with opacity tables generated using the open-source code `NuLib`.[27]

The metric evolved in `GR1D` is Schwarzchild-like:

$$\begin{aligned} ds^2 &= g_{\mu\nu}x^\mu x^\nu \\ &= -\alpha(r,t)^2dt^2 + X(r,t)^2dr^2 + r^2d\Omega^2, \end{aligned} \tag{6}$$

where α and X can be expressed as functions of a metric potential ϕ (which reduces to the Newtonian potential in the Newtonian limit) and the enclosed gravitational mass $M_{\rm grav}$:

$$\begin{aligned} \alpha(r,t) &= \exp[\phi(r,t)], \\ X(r,t) &= \left(1 - \frac{2M_{\rm grav}(r,t)}{r}\right)^{-1/2}. \end{aligned} \tag{7}$$

For the present work, we first note that turbulence is mostly relevant far from the proto-neutron star (PNS) where GR effects can be treated as a perturbation. Therefore, one can simply make a few changes to the terms in Eq. (1) without having to re-derive the entire Reynold's decomposition. The expression for $\omega^2_{\rm BV}$, however, must be carefully re-derived. Far from the PNS, we invoke the following:

(1) replace the conserved variable ρ with its GR counterpart, i.e. $D = WX\rho$, where $W = (1-v^2)^{-1/2}$ and $v = Xv_r$;
(2) multiply the RHS of Eq. (1) by αX.
(3) multiply the spatial flux in Eq. (1) by α/X (see Ref. [26] for more details on the derivation of the hydrodynamic equations in `GR1D`).

The expression of $\omega^2_{\rm BV}$ can be derived using conservation of momentum for a convective eddy in a background fluid in hydrostatic equilibrium. The case of a fluid with non zero acceleration can be derived with ad-hoc corrections for general relativistic effects. The derivation can be found in Ref. [1], and it leads to:

$$\omega^2_{\rm BV} = \frac{\alpha^2}{\rho h X^2}\left(\frac{{\rm d}\phi}{{\rm d}r} - v\frac{\partial v}{\partial r}\right)\left(\frac{\partial \rho(1+\epsilon)}{\partial r} - \frac{1}{c_s^2}\frac{\partial P}{\partial r}\right), \tag{8}$$

where $v = Xv_r$.

The main difference between Eqs. (3) and (8) is the inclusion of $\partial\rho\epsilon/\partial r$ in the latter. In the gain region the internal energy decreases with radius, i.e. $\partial\rho\epsilon/\partial r < 0$. This decreases the magnitude of $\omega_{\rm BV}$ and therefore the amount of turbulence that is generated. We will come back to this in Section 3.2

3. Results: Comparison with 3D simulations

3.1. *Results using an effective potential*

Inspired by the work of CWO20, we compare our GREP model to the `mesa20_LR_v` 3D simulation,[28] by using the same setup chosen by CWO20. That is, we simulate

the collapse of a 20 $M_\odot$ progenitor from,[29] adopting the SFHo EOS[30] and assuming Nuclear Statistical Equilibrium (NSE) everywhere. The algorithm used in `FLASH` to solve the neutrino radiation transport closely resembles the one used in `GR1D`.[27] Additionally, the set of `NuLib` opacities we adopted is the same used by CWO20. Finally, we use 12 neutrino energy groups geometrically spaced up to ∼250 MeV.

The upper panels of Figure 1 (modified from Ref. [1]) show the shock radius versus time and the turbulent velocity profile at ∼135 ms post-bounce for our GREP model (to be compared to Figures 1 and 2 of CWO20). The main difference between our results using `GR1D` and the ones from CWO20 using `FLLASH` is that `GR1D` consistently gives larger values for the turbulent velocity at a given $\alpha_{\rm MLT}$. This then translates into larger shock radii at a given time. Except for these small differences, the agreement between the two models is very good, and both yield explosions for $\alpha_{\rm MLT} \gtrsim 1.2$.

When it comes to the comparison with the 3D results, however, our MLT-like model does not captures some features that are present in the 3D case. Specifically, the profile at ∼135 ms post-bounce of the convective speed in 3D has a longer tail at 50-80 km. This has already been noticed by CWO20, and it is due to angular variations present in the 3D model, rather than a deeper convection extending in the region below the gain layer. In our model, convection shuts off at 80 km, as one would expect, since that is approximately the location of the gain layer. A more interesting difference is the lack of PNS convection at 25 km, not captured by our MLT-like model. A possible explanation for this is that STIR is not taking lepton number-driven convection into account, which is not easily tractable with MLT models, and therefore a more careful treatment of this type of convection might ease the discrepancy with the 3D results. We are currently working on adjusting some of the parameters of STIR deep inside the PNS to match the 3D result, and therefore analyze the impact of PNS convection on the explosion, but this goes beyond the scope of this conference proceedings.

3.2. *Results using GR*

One can compare the results obtained using the simple GREP approach with results in full GR. We show the results using full GR in the bottom panels of Figure 1, while the upper panels refer to the runs using our GREP model. The most important difference to point out is the range of $\alpha_{\rm MLT}$ used in the GR and GREP simulations. To produce shock radii and turbulent velocities that are similar to the GREP results, the value of $\alpha_{\rm MLT}$ that needs to be used in full GR is ∼ 20% larger. The reason behind this increase in $\alpha_{\rm MLT}$ lies in the expression of $\omega_{\rm BV}$. As pointed out in Section 2.2, including the internal energy gradient into eq. (8) is the main difference between the GREP and GR models.

In the gain region, where turbulent convection is most relevant, the gradient of the internal energy is negative. This decreases the magnitude of $\omega^2_{\rm BV}$, making the fluid more stable against convection. Including $\rho\epsilon$ in the definition of $\omega_{\rm BV}$ is hence

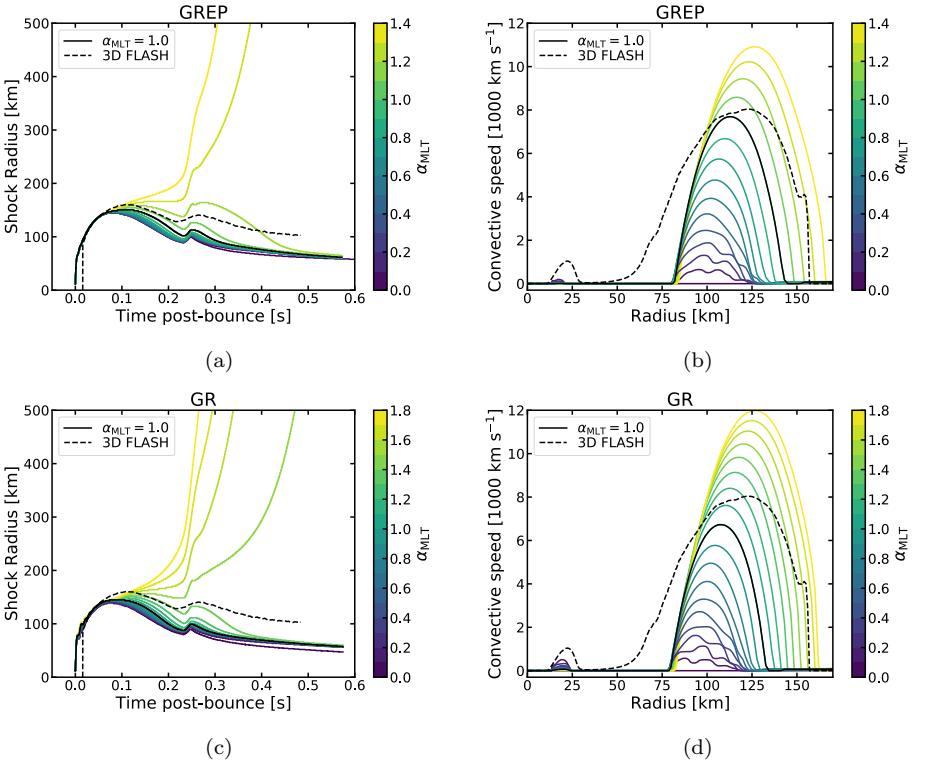

Fig. 1. The plots on the upper row were generated using our GREP model, while the plots on the bottom row were generated using full GR. Panels (a,c) show the time evolution of the shock radius for different values of the parameter $\alpha_{\rm MLT}$, and can be compared to Figure 2 from CWO20. Panels (b,d) show a snapshot at ~ 135 ms post bounce of $v_{\rm turb}$, and can be compared to Figure 1 from CWO20. The dashed lines represent the 3D simulation from Ref. [28].

needed to realistically characterize turbulent convection. If one takes the form of $\omega_{\rm BV}$ from Eq. (8) and implements it in the GREP model, the value of $\alpha_{\rm MLT}$ needed to achieve an explosion increases, becoming comparable to the one used in the GR model.

3.3. *Progenitor Study*

In the previous Sections we summarized the validation of our turbulent convection model[1] by comparing it to the 3D results of Ref. [31]. In this section, we summarize the use[1] of our calibrated models to simulate the collapse and subsequent shock revival of 20 progenitors from Ref. [32]. We use three different values of $\alpha_{\rm MLT}$, for which the fraction of successful explosions is roughly between 25% and 80%.

Our GREP model generates results[1] that are compatible with the ones obtained by CWO20 shifted by $\Delta\alpha_{\rm MLT} \simeq 0.05$. If one compares the left panel of Figure 2 with Figure 6 from CWO20, it is clear that our model tends to yield explosions for

slightly smaller values of $\alpha_{\rm MLT}$. This shift mainly depends on two differences between our model and the one from CWO20: (i) we used a finer resolution in space and energy; (ii) the numerical algorithms used to solve the hydrodynamic equations and the neutrino transport are different.

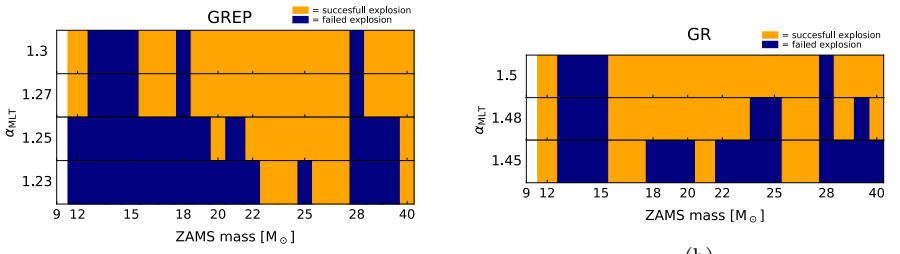

Fig. 2. Explosion pattern (modified from Ref. [1]) of CCSN for the GREP (left panel) and GR (right panel) models as a function of the Zero Age Main Sequence mass. Orange bands represent successful explosions (i.e. the shock has reached 500 km), while dark blue bands represent failed explosions.

Even more importantly, Figure 2 shows that a General Relativistic treatment of turbulent convection does not simply reproduce the results obtained by the GREP model. By looking at Figure 1 one might conclude that, since the value of $\alpha_{\rm MLT}$ required to generate an explosion in GR is larger, using GR with larger values of $\alpha_{\rm MLT}$ would produce the same patterns shown in the left panel of Fig. 2. However, that is not the case, and GR modifies the explosion pattern of CCSNe. To even more accurately characterize the differences between the patterns of explodability in the GR and GREP models, a systematic study with hundreds of progenitors and more values of $\alpha_{\rm MLT}$ would be desired. That, however, is beyond the scope of this conference proceedings.

We can conclude from Figure 2 that general relativity changes which progenitors are more likely to explode. By focusing on the patterns associated with $\alpha_{\rm MLT} = 1.27$ and $\alpha_{\rm MLT} = 1.48$ one can see that, using the GREP model, the 24, 25 and 30 $M_\odot$ progenitors explode, whereas the 18 $M_\odot$ doesn't. In the GR model it is the exact opposite. It should be pointed out that the pattern of explodability generated by the GR model with $\alpha_{\rm MLT} = 1.48$ is intermediate between the results of CWO20 and Ref. [32]: (i) like the former (but unlike the latter), it shows failed explosions for low mass progenitors with M = 13-15 $M_\odot$; (ii) like the latter (and unlike the former) it shows that higher mass progenitors with M = 24-25 $M_\odot$ result in failed explosions.

It is worth mentioning that the explodability pattern obtained using the GR model with $\alpha_{\rm MLT} = 1.48$ cannot be reproduced by the GREP model. One can see that, from the left panel of Figure 2, for $\alpha_{\rm MLT} = 1.23$, the 25 $M_\odot$ progenitor fails, and all progenitors below 22 $M_\odot$ fail as well. This shows that the GREP model

cannot produce successful explosions for progenitors with masses 15-18 $M_\odot$ and at the same time failed explosions of the 24-25 $M_\odot$ progenitors, like we see in the right panel of Figure 2. Notably, the GR model with $\alpha_{\rm MLT} = 1.5$ reproduces the same pattern of explodability found in the GREP model with $\alpha_{\rm MLT} = 1.27$ (with the only exception of the 18 $M_\odot$ progenitor). This tells us that: (i) the threshold between failed and successful explosions is a steep function of $\alpha_{\rm MLT}$; and (ii) GR can reproduce the GREP results for large values of $\alpha_{\rm MLT}$ and large explosion fractions.

Overall, our results[1] have shown that including general relativistic effects can modify how turbulence behaves in a one-dimensional, MLT-like model. It is hard to predict if this effect will translate to multi-dimensional simulations, given the differences between 1D and multi-D. Nonetheless, these results suggest that GR (as opposed to GREP) can have a significant impact on the explosion of CCSNe. A detailed comparison between full-GR and Newtonian simulations, performed with 2D and 3D codes across multiple progenitors, will clarify whether this effect translates to higher dimensions, where turbulent convection is generated self-consistently.

4. Conclusions

In this proceedings contribution we have summarized our development[1] of extended *STIR*, the MLT-like model of CWO20, to a full general relativistic formalism. Our implementation of STIR in `GR1D` can reproduce the results of CWO20 when using the same GREP model that they developed. The GR version of STIR needs larger values of $\alpha_{\rm MLT}$ to achieve shock dynamics that are similar to the ones obtained with a GREP model.[1] The reason behind this is that, as can be seen from Eq. (8), one needs to include the gradient of the internal energy gradient in the expression for $\omega_{\rm BV}$. This reduces the magnitude of $\omega^2_{\rm BV}$ in the gain region, which inhibits the generation of turbulence. The net result is that larger values of $\Lambda_{\rm mix}$ (and therefore of $\alpha_{\rm MLT}$) are needed to develop a convective mixing that is as strong as the one obtained without the inclusion of GR.

After comparing our model to the 3D results of Ref. [28], we simulated[1] the collapse and subsequent shock expansion of 20 different progenitors[32] for different values of $\alpha_{\rm MLT}$, for both the GREP and GR models. Our main finding[1] is that GR changes the pattern of explodability of CCSNe. Specifically, the 24 $M_\odot$ and the 25 $M_\odot$ progenitors need comparatively much larger values of $\alpha_{\rm MLT}$ to explode with the GR model. This produces an explodability as a function of progenitor mass that is intermediate between the results of CWO20 and Ref. [32]. However, the GR model also shows, for values of $\alpha_{\rm MLT}$ that yield large explosion fractions (i.e. $\alpha_{\rm MLT} = 1.5$), an explodability that is compatible with the results obtained using the GREP model.

As a neutron star spins down mechanical strain accumulates in the solid crust up to and beyond the point of failure. To model the repeated macroscopic failure of the crust an idealised cellular automaton is developed, with nearest-neighbour interactions representing strain dissipation and redistribution, and including thermal losses. The probability distribution functions (PDFs) of the size and waiting times of failure events in the automaton are presented. The final failure event of a star's life occurs when the star spins down to $\approx (5 \pm 3)\%$ of its birth frequency with implications for transient events e.g. rotational glitches. In addition the automaton is able to predict the star's mass-quadrupole moment and gravitational wavestrain at all points in the star's life, with relevance to future gravitational wave surveys such as those carried out with the Laser Interferometer Gravitational Wave Observatory (LIGO).

Keywords: Asteroseismology – gravitational waves – stars: evolution – stars: neutron – stars: rotation

1. Introduction

The mechanical failure of the crust of a rotating neutron star, and the associated creation of mountains, has been suggested as a source of continuous gravitational waves,[1–3] and transient events such as rotational glitches[4,5] and fast radio bursts.[6] No such gravitational waves have been observed despite multiple recent searches,[7–13] but theoretical arguments exist that the first detection is close.[2] It should be noted that other reasonable explanations for transients have been suggested, e.g. superfluid vortices in the context of glitches.[14,15]

The macroscopic, tectonic process by which the crust fails and mountains form is unknown.[16,17] By analogy with the Earth, one expects crustal failure to involve large-scale, inhomogeneous elements such as fault lines, plates, subduction zones, stress zones, and so on, even though the tensile properties of a neutron star's crust are likely to be different to those of terrestrial rocks (and indeed are not understood completely at present). Modelling has primarily focused on the microphysics of crustal failure.[18–22] In particular Ref. 19 found local cracking does not occur due to the extreme pressure and the crust material fails globally. There have been some investigations into the evolution of the whole star as it evolves through a quasistatic sequence of elastic equilibria.[23,24,31] However, these do not consider the impact of the stick-slip dynamics of repeated local failures involving inhomogenous tectonic features, e.g. tectonic plates, which lead to history dependent outcomes.

Here we present a model of local mountain formation caused by mechanical failure of the crust on macroscopic scales driven by spin down. The model describes the tectonics of crustal failure through a cellular automaton, similar in spirit to the block-and-spring automata used to describe the far-from-equilibrium, stick-slip dynamics of terrestrial earthquakes.[25] Section 2 deals with how the crust deforms due to spin down, the consequent strain build up, and the effects of repeated local failures. Section 3 briefly presents some of the results of this model, in particular the probability distribution functions (PDFs) of the heat dissipated in failure events and the time between events. Section 4 presents the gravitational wavestrain over time as a function of the automaton parameters. For simplicity we do not consider a magnetic field, which is unlikely to be important in ordinary neutron stars (although this may not be true in magnetars).

This paper summarises the key aspects of the model and its output as developed in Ref. 26. This summary borrows heavily from the structure and content of Ref. 26. Among other things, Figs. 1 and 2 are reproduced from the latter reference.

2. Tectonics of Mountain Formation

2.1. *Global deformation due to spin down*

A neutron star is composed of a superfluid core and a solid crystalline crust.[21,22,27–30] Other components, e.g. transitional layers containing nuclear pasta at the crust-core interface,[16] are neglected here for simplicity.

As a neutron star spins down the balance of centrifugal and gravitational forces changes and so does the equilibrium figure of the crust. We use the method of Ref. 31 to model the secular deformation due to spin down, which in turn allows for the calculation of the mechanical strain at every point in the crust. In Ref. 27 Eqs. (3)-(8) define a vector which describes the change in the star's equilibrium figure due to spin down from which the mechanical strain can be calculated, see also Eqs. (1)-(7) in Ref. 26.

2.2. *Local microscopic failure*

We propose that the strain built up over the course of spin down causes the crust to fail locally when strained beyond breaking, and that some fraction of the energy released from the strained crystal lattice of the crust causes the centre of mass of the failed section to move radially outwards, creating a mountain.

Estimates of the breaking strain of neutron star crust material vary many orders of magnitude, e.g. Ref. 32 found a breaking strain of $\sim 10^{-5}$ and the more recent results of Ref. 19 instead found a breaking strain of ~ 0.1. We follow the results of Ref. 19 and consider a breaking strain in the range 0.075 to 0.11. Additionally Ref. 19 found that the material fails in a global manner, i.e. local cracks do not form, but the simulation volume is $\sim 10^{11}$ fm^3 and the macroscopic crust likely behaves differently (see Sec. 2.3 in this paper and Sec. 2.3 in Ref. 26).

When the crust fails it deforms plastically. When a material is deformed plastically a fraction of the plastic work done, β, is dissipated as heat. The value of β depends on a variety of factors such as the material, current strain, strain rate, and deformation history.[33–37] As per Ref. 35 terrestrial metals such as copper and steel have $0.75 \lesssim \beta \lesssim 0.95$, however such metals are unlikely to be good analogues for neutron star crust material. It is extremely difficult to calculate a realistic value of β and we do not attempt to do so. Instead we conservatively set $\beta = 0.9$, taking the position that the significant majority of the plastic work done is dissipated as heat.

2.3. *Repeated global failure: An automaton*

Ref. 19 found, using a direct simulation of nucleonic crystal (neutron star crust material), that the material fails in a global sense. Due to the extreme pressure local failure, i.e. cracking, is not observed. However the simulation volume is $\sim 10^{11}$ fm^3 and the macroscopic crust likely behaves differently, as noted in Sec. 2.2. In reality there are likely to be macroscopic features like seismic faults. To model these stick-slip and stress-relax dynamics[25] we create an automaton.

We divide the crust into N discrete cells; cells are indexed by i, with $0 \leq i < N$, and have position (r_i, θ_i, ϕ_i). The half-annular shape of the cells (dictated by assumed symmetry) and their coordinates are discussed in detail in Sec. 2.3 and Appendix A of Ref. 26. Each cell is assigned a breaking strain, σ_i, uniformly randomly between 0.075 and 0.11, informed by the stress-strain curve calculated in Ref. 19. Strain is greatest at the base of the crust, so the elastic potential energy density is greatest there too. As such the strain of each cell is evaluated at the base of the crust.

Over the course of spin down the strain of each cell, γ_i, increases. We define failure as when a cell has strain equal to or greater than its breaking strain, $\gamma_i \geq \sigma_i$. A failed volume of material is less able to support mechanical loads and so shifts the load to the neighbouring volume.[38] To model this we implement a nearest-neighbours interaction. Upon failure adjacent cells receive a fraction of the strain "lost" by the failed cell, with

$$\gamma_{i\pm1} \mapsto \gamma_{i\pm1} + \frac{1}{3}D(1-A)\gamma_i, \tag{1}$$

$$\gamma_{N-1-i} \mapsto \gamma_{N-1-i} + \frac{1}{3}D(1-A)\gamma_i, \tag{2}$$

where $0 \leq D \leq 1$ and $0 \leq A \leq 1$ are constants of the automaton, and cells indexed by $i = 0$ and $i = N-1$ are adjacent.[a] $(1-A)\gamma_i$ is the amount of strain "lost" by cell i upon failure. Some portion of the released strain, $D(1-A)\gamma_i$, is redistributed amongst cell i's nearest neighbours as per Eqs. (1) and (2). The remaining portion

[a]The cells closest to the North pole, $i = 0, N-1$, and South pole, $i = \lfloor N/2 \rfloor$ for N odd, or $i = N/2, N/2-1$ for N even, are adjacent to two cells not three. As such during strain redistribution Eq. (2) does not apply and Eq. (1) should be evaluated with a factor of 1/2 rather than 1/3.

of strain, $(1-D)(1-A)\gamma_i$, is converted into plastic work deforming the crust, i.e. moving cell i. After the strain of the failed cell's nearest neighbours is increased the failed cell's own strain is updated accordingly,

$$\gamma_i \mapsto A\gamma_i. \tag{3}$$

The quantity A is the fraction of strain a failed cell retains upon failure, and D is the fraction of strain released from the failed cell that is redistributed to the nearest neighbours. We call A and D the "dissipation" and "redistribution" parameters respectively.

In the failure process described above the crust is deformed plastically. The failed cell i is moved purely radially (θ_i and ϕ_i are unchanged) a distance Δr_i to model the plastic deformation,

$$r_i \mapsto r_i + \Delta r_i. \tag{4}$$

Δr_i is calculated by equating the energy associated with plastic deformation with the work done moving the cell against the gravitational-centrifugal potential a distance Δr_i. The potential is given by[31]

$$\Phi(\vec{r}) = -\pi G\rho_{\text{core}}\left[2R^2 - \frac{2r^2}{3} - \frac{4e^2r^2}{15}P_2(\cos\theta)\right], \tag{5}$$

where G is the gravitational constant, ρ_{core} is the density of the fluid core, and e is the eccentricity of the ellipse defined by the meridional cross-section of the star.

In general the mechanical potential energy U stored in a body of volume V under a strain γ is given by the strain-energy formula

$$\frac{\mu\gamma^2}{2} = \frac{U}{V}, \tag{6}$$

where μ is the shear modulus of the material. The mechanical potential energy density of a given cell i is then $\mu\gamma_i^2/2$. As described above if a given cell i with strain γ_i fails then the amount of strain that is converted into plastic work is $(1-A)(1-D)\gamma_i$. We calculate Δr_i from

$$\frac{\mu(1-\beta)}{2}[(1-A)(1-D)\gamma_i]^2 = \Delta r_i\rho_{\text{crust}}\left.\frac{d\Phi(\vec{r})}{dr}\right|_{\vec{r}=\vec{r}_i}, \tag{7}$$

where ρ_{crust} is the density of the crust, and β is the coefficient of thermal dissipation. As per Sec. 2.2 we take the conservative position of $\beta = 0.9$, i.e. we assume the significant majority of the plastic work done on the crust during failure is dissipated as heat.

The state of each cell in the automaton is described by five numbers $[r_i(t_n), \theta_i(t_n), \phi_i(t_n), \gamma_i(t_n), \sigma_i(t_n)]$, which are updated at each time-step. Here the i index refers to the cell index and t_n corresponds to the time-step. The initial shape of the star is a Maclaurin spheroid with eccentricity $e = 0.1$, a representative value.

The specific steps of the automaton are given:

(1) Choose the values of A and D.
(2) Initialise $[r_i(t_0), \theta_i(t_0), \phi_i(t_0)]$.
(3) Randomly assign each cell a breaking strain in the range $0.075 \leq \sigma_i \leq 0.11$, and set $\gamma_i = 0$.
(4) Using the method of Ref. 31 calculate the deformation vectors and increase the strain of each cell for a small spin down of $\delta\Omega$ and the fiducial values below in Sec. 2.4.
(5) If a cell i has $\gamma_i \geq \sigma_i$ then it undergoes failure.
    (a) Redistribute the strain of failed cell i to its nearest neighbours as per Eqs. (1) and (2) synchronously, i.e. all cells with $\gamma_i \geq \sigma_i$ are identified and fail simultaneously before Eqs. (1) and (2) are applied.
    (b) Move cell i radially as per Eqs. (4) and (7).
    (c) Decrease the strain in cell i as per Eq. (3).
    (d) Assign to cell i a new breaking strain, uniformly randomly in the range $0.075 \leq \sigma_i \leq 0.11$.
    (e) Repeat the steps (5)(a) to (5)(e) until $\gamma_i < \sigma_i$ for all $0 \leq i < N$.
(6) Decrease Ω by $\delta\Omega$.
(7) Repeat from step (4) until one has $\Omega \leq \delta\Omega$.

2.4. *Fiducial parameters*

The fiducial values used for this automaton are: $\mu = 2.4 \times 10^{29}$ Jm^{-3}, total radius $R = 10.5$ km, crust-core radius $R' = 9.5$ km, $\rho_{\rm core} = 6.38 \times 10^{17}$ kgm^{-3}, $\rho_{\rm crust} = 10^{17}$ kgm^{-3}, total stellar mass of 1.4 solar masses, $\Omega(0)/2\pi = 800$ Hz, and $\dot{\Omega}(0)/2\pi = -1 \times 10^{-8}$ Hzs^{-1}. For $A = D = 0.5$ and the above fiducial values the failure of a cell on the equator with $\sigma_i = 0.1$ leads to $\Delta r_i \approx 0.04$ mm. For the purpose of calculating the gravitational wavestrain we consider a star that is a distance $d = 1$ kpc away from the Earth.

In this automaton we set $N = 400$. The typical angular velocity step per automaton time-step is $\delta\Omega = (1.25 \times 10^{-4})\Omega(0)$. To convert $\Omega(t)$ into time t in what follows, we use $\Omega(t) = \Omega(0)(1 + t/\tau)^{-1/2}$ where $\tau = -\Omega(0)/2\dot{\Omega}(0) = 4 \times 10^{10}$ s, is the electromagnetic spin-down timescale.

3. Event Statistics

The automaton allows for the location of every part of the crust to be known at every point in time over the course of the star's life. Additionally the time, location, and energy of failure events are tracked. Numerous observables are studied as functions of t in Ref. 26. In Sec. 3.1 we focus on the PDF of event sizes. The PDF of the time between one event and the next one (the waiting time) and the age of the star at which tectonic activity ceases are presented in Sec. 3.2, and the correlation between event size and waiting time is presented in Sec. 3.3.

3.1. *Size PDF*

Mechanical failure of the crust has been linked to multiple types of transient events such as rotational glitches,[4,5] soft gamma-ray repeaters[22,39,40] and fast radio bursts.[6] Testable models of the transients' statistics, such as the automaton presented here, are needed to differentiate between crustal failure and other viable explanations of the transients e.g. superfluid vortices in the context of rotational glitches.[14,41–44]

In the upper panel of Fig. 1 we present the PDFs for the heat dissipated in an event, i.e. its size, given as ΔE. The left-hand side of Eq. (7) gives the amount of energy done as plastic work on the crust not lost as heat. Thus multiplying by $\beta/(1-\beta)$ gives the energy that is dissipated as heat in a failure event. The qualitative form of the PDF is similar across parameter space, a tight peak with a tail in increasing ΔE. Close to $A = D = 0$ events are largest with $\langle \Delta E \rangle \approx 5.4 \times 10^{36}$ J and the tail is most strongly suppressed; events with $\Delta E > \langle \Delta E \rangle$ are relatively less likely than in other regions of parameter space. Close to $A = D = 1$ events are smallest with $\langle \Delta E \rangle \approx 1.9 \times 10^{33}$ J and the tail is much more pronounced; events with $\Delta E > \langle \Delta E \rangle$ are relatively more likely than in other regions of parameter space. The decrease in $\langle \Delta E \rangle$ with increasing A and D follows from Eq. (7). The change in the tail comes from larger A and D more easily facilitating avalanches. More frequent avalanches means larger events are more frequent. For larger A cells remain close to critical after failure, and are thus more prone to fail when a neighbour does. For larger D the nearest-neighbours interaction is simply stronger.

3.2. *Waiting-time PDF*

We define the waiting time of an event, Δt, as the time between that event and the next one. In the lower panel of Fig. 1 we present the PDFs of waiting time for a variety of values of A and D. There is a steep rise for small Δt with an approximately exponential tail for high Δt, the probability density peaks at $\Delta t \approx 0.1\tau$. Recall τ is the spin-down timescale as defined in Sec. 2.4. The waiting-time PDF is approximately exponential, with the peak at $\Delta t \approx 0.1\tau$ an artifact of time discretisation. The frequency decrement, $\delta\Omega$, is constant. Correspondingly the time-steps are small early in the star's life and large later on. As such short waiting-time events are restricted to early in the star's life whereas long waiting-time events can happen throughout. In contrast to the PDF of event sizes the PDF of waiting times is unaffected by A or D. This is because the driver of events is the rate of strain build up, which is governed by spin down and unaffected by A or D.

In order for failure to occur at all we find that the star must be born with an initial rotational frequency $\gtrsim 750$ Hz, consistent with the results of Ref. 27. However once failure does occur, it continues until the star is near totally spun down, $\approx 5 \pm 3\%$ of the birth frequency, i.e. $t/\tau \approx 100$ to 2500. This is because the only way for strain to exit the system is through failure events, it otherwise continually builds up.

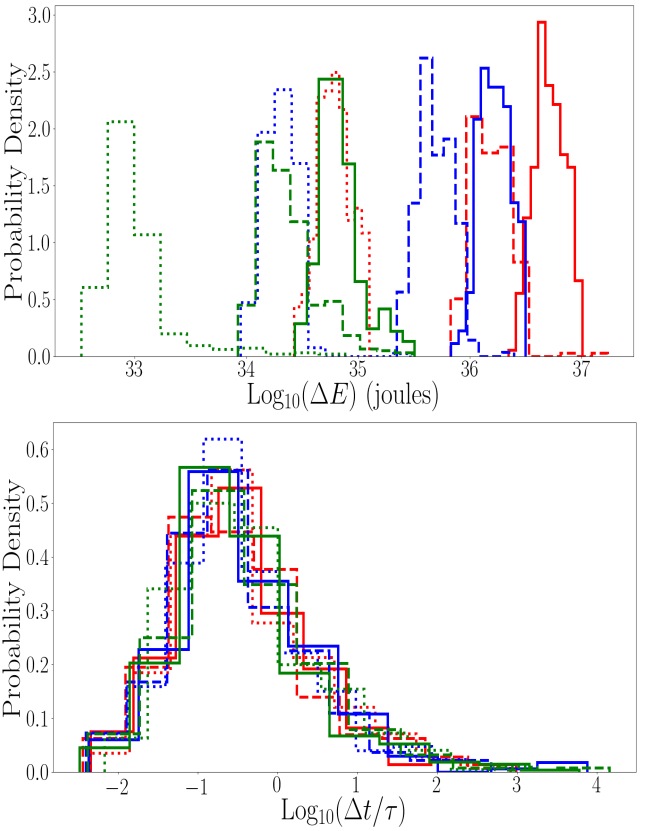

Fig. 1. Size PDFs, measured in joules, for a range of A and D (top panel). Waiting-time PDFs, measured in units of spin-down timescale, τ, for a range of A and D (bottom panel). In both panels red corresponds to $A = 0.1$, blue to $A = 0.5$ and green to $A = 0.9$. The solid lines correspond to $D = 0.1$, dashed to $D = 0.5$ and dotted to $D = 0.9$. Each PDF is constructed from all the events from five simulations. This figure is copied from Ref. 26.

3.3. *Size-waiting-time correlations*

Also of interest are the correlations between the size of an event and the waiting time (recall the waiting time is the time until the next event). We find that the Spearman rank coefficient is ≈ 0.3 uniformly across parameter space. On average larger events affect more of the crust and so, post-failure, cause a larger fraction of the crust to be further from failure, meaning that the average time until the next event is longer. However larger events do not necessarily affect more of the crust, due to the random breaking strains of cells, causing the correlation to be weak. Additionally it is possible for a large event to simply not involve the next-closest-to-failure cell and thus do nothing to delay the next event, further weakening the correlation.

4. Gravitational Radiation

Continuous gravitational waves are the subject of many recent, albeit unsuccessful, searches.[7–13] As such we are motivated to calculate the signal expected from possible sources. Here we consider an isolated spinning-down neutron star with mountains forming due to mechanical failure of the crust. Other potential sources of continuous waves include X-ray binaries[45] and accreting neutron stars.[46] In this model the location of every part of the crust, and the rotational frequency, is known for all of the star's life, so the gravitational wavestrain can be calculated at all times.

In Fig. 2 we plot the wavestrain over time from a neutron star. The two dynamical factors that determine the wavestrain are the changing failure-induced mass-quadrupole moment and the decaying rotational frequency, with $h_0 \propto Q\Omega(t)^2/d$, where h_0 is the gravitational wavestrain, Q is the mass-quadrupole moment, and d is the distance from Earth. At early times spin down is rapid, causing strain to accumulate quickly and many failures to occur, leading to a rapid increase in Q, thus causing the sharp initial rise in Fig. 2. As the star spins down $\dot{\Omega}(t)$ decreases, this slows the rate of mountain creation and causes Q to increase more slowly. At $t/\tau \approx 5$ to 10 the effect of increasing Q balances with the effect of decreasing $\Omega(t)$, causing the wavestrain reach its maximum value. After the peak in wavestrain the decreasing frequency leads to $h_0 \propto (1 + t/\tau)^{-1}$ for $t \gtrsim 10\tau$.

Similar to the size of events the wavestrain is largest near $A = D = 0$ peaking at $h_0 \approx 5 \times 10^{-28}$ and smallest near $A = D = 1$ peaking at $h_0 \approx 1.6 \times 10^{-31}$. Larger events create larger mountains and so lead to a greater waverstrain. Wavestrain reaches a maximum at $t/\tau \approx 5$ to 10, corresponding to $\Omega(t)/2\pi \approx 250$ to 320 Hz. There is no trend with A or D in when the wavestrain peaks. The timing of the peak

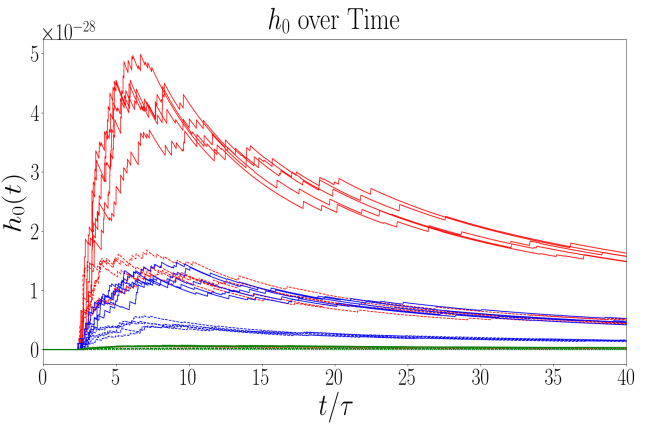

Fig. 2. Gravitational wavestrain, $h_0(t)$, as a function of time, t, in units of the spin-down timescale τ. Each line is the wavestrain of an individual run, of which there are five per value of (A, D). Red corresponds to $A = 0.1$, blue to $A = 0.5$ and green to $A = 0.9$. The solid lines correspond to $D = 0.1$, dashed to $D = 0.5$, dotted to $D = 0.9$. This figure is copied from Ref. 26.

is determined by the rate of events and spin down, neither of which is impacted by A or D.

It should be noted that spin down induced-failure is not the only potential source of mountains on neutron stars. Mountains may form on accreting stars[46] and r-mode oscillations may also lead to a detectable current-quadrupole gravitational wave signal.[47]

5. Conclusion

Electromagnetic spin down drives centrifugal crustal deformation and repeated crustal failure in rotation-powered pulsars. Crustal failure may be responsible for impulsive phenomena like rotational glitches.[4,5] It may also create mountains which lead to the continuous emission of gravitational radiation.[1–3] Molecular dynamics simulations reveal that the crust fails homogeneously, without cracking, under the high pressures on neutron stars.[19] However the simulations are conducted on picometre scales and cannot resolve inhomogeneities on macroscopic length scales (e.g. $\gtrsim 1$ m) such as tectonic plates, faults, and so on, which are seeded by dislocations and other impurities and grow under repeated failure. In this paper, we develop a phenomenological model in the form of a cellular automaton to capture - in a highly idealised form - some of the far-from-equilibrium physics of repeated failure.

We present an idealised cellular automaton to model the evolution of the crust as it both spins down secularly and deforms plastically due to mechanical failure. The secular deformation and strain build up are modelled using the method of Ref. 31. We make use of a nearest-neighbours interaction to model the redistribution and dissipation of strain and the plastic deformation following crustal failure, including the effects of thermal dissipation.

In this model the time, location and size of every failure event are known, as is position of every part of the crust at every point in time. This allows for a wide variety of observables to be predicted, e.g. total tectonic activity, rate of tectonic activity, and number of events. These observables, among others, are investigated in greater detail in Ref. 26. We find the ΔE PDF is qualitatively similar for all values of A and D, namely a tight peak with a tail in increasing ΔE. Events are largest near $A = D = 0$ with $\langle \Delta E \rangle \approx 5.4 \times 10^{36}$ J and smallest near $A = D = 1$ with $\langle \Delta E \rangle \approx 1.9 \times 10^{33}$ J. The gravitational wavestrain follows a similar pattern due to larger events creating larger mountains. The maximum emitted wavestrain in the star's life is greatest near $A = D = 0$ with $h_0 \approx 5 \times 10^{-28}$ and smallest near $A = D = 1$ with $h_0 \approx 1.6 \times 10^{-31}$. In contrast we find that the waiting-time PDF is insensitive to A and D.

The key predictions of this model are (i) in order for failure to occur at all the star must be born spinning $\gtrsim 750$ Hz, consistent with the results of Ref. 27, (ii) once the first failure has occurred failures will continue until $\Omega(t) \approx (0.05 \pm 0.03)\Omega(0)$, and (iii) there is a weak positive correlation (Spearman rank coefficient ≈ 0.3) between the size of an event and the time until the next one.

We plan to improve this calculation in future. Refs. 23 and 24 extend the formalism of Ref. 31. These extensions account for the stratification of the star i.e. they allow for the consideration of a star of multiple variously dense layers, rather than requiring a two component crust-core formulation, additionally they model perturbations from chemical equilibrium.

Some particle physics models with an additional $U(1)$ gauge interaction are interesting because those address the origin of neutrino masses. We show that, in a wide class of models, such an extra $U(1)$ gauge symmetry breaking in the early universe can be first-order phase transition and hence generate a detectable amplitude of stochastic gravitational wave radiation in future experiments. We also discuss the parameter dependence and a possible UV completion.

Keywords: Gravitational waves; Beyond the standard model.

1. Introduction

The detection of gravitational waves (GWs) provides information on the evolution of the Universe at an early stage. Cosmological GWs could originate from, for instance, quantum fluctuations during inflationary expansion[1] and phase transitions.[2,3] The first-order phase transition in the early Universe is one of the promising sources of GWs stochastic background.[4–6] After a first-order phase transition, the dynamics of bubble collision[7–11] and subsequent turbulence of the plasma[12–16] and sonic waves generate GWs.[17–19] These might be within the reach of future space interferometer experiments such as the Big Bang Observer (BBO)[20] and DECi-hertz Interferometer Observatory (DECIGO)[21]; or even ground-based detectors such as Advanced LIGO (aLIGO),[22] and Einstein Telescope (ET),[23] if the transition temperature is below $\mathcal{O}(10^7)$ GeV.[24–26]

One of the important open questions in particle physics is the origin of nonvanishing neutrino masses established by various neutrino oscillation phenomena. The most attractive idea for explaining the tiny neutrino masses is the so-called seesaw mechanism with heavy Majorana right-handed (RH) neutrinos N_R.[27–30] From analogy to the fact that masses of gauge bosons and fermions in the standard model (SM) of particle physics are generated by the breakdown of the electroweak SM gauge symmetry, it is natural to suppose that the masses of heavy RH neutrinos are also generated by developing the vacuum expectation value (VEV) of a Higgs field which breaks a certain symmetry at a high energy scale.

Our Universe has undergone several phase transitions since its birth. The well-known examples are the quark-hadron, aka QCD, transition and the electroweak phase transition. Other promising transitions would be associated with the generation of RH neutrino Majorana masses, and the breakdown of the Great Unified Theory (GUT) gauge symmetry.

The spectrum of stochastic GWs produced by the first-order electroweak phase transition with an extended Higgs sector has been investigated due to interest in the electroweak baryogenesis.[4–6] Among GWs generated by an extra $U(1)$ symmetry breaking,[31–41] one of the simplest and the most promising symmetry is the gauged $U(1)_{B-L}$ (baryon number minus lepton number) symmetry,[42–45] since the SM also poses the $B-L$ symmetry as an accidental global symmetry. In the standard $U(1)_{B-L}$ charge assignment, three RH neutrinos must be introduced to satisfy the conditions for cancellation of the gauge and gravity anomaly. The $U(1)_{B-L}$ may come from a larger GUT symmetry.

In the case that the $U(1)_{B-L}$ symmetry breaking takes place at an energy scale higher than the TeV scale, it is very difficult for any collider experiments to address the mechanism of the symmetry breaking and the RH neutrino mass generation. On the other hand, GWs from the first-order phase transition associated with the spontaneous $U(1)_{B-L}$ gauge symmetry breaking can probe the mechanism. This is what we point out here. For GWs generated by a TeV scale $U(1)_{B-L}$ phase transition, see literature.[32,33,38]

First, we investigate GWs from the first-order phase transition associated with the spontaneous $U(1)_{B-L}$ gauge symmetry breaking within the minimal Higgs model[39] and a non-minimal Higgs model.[35] We show that the first-order phase transition of the Higgs $B-L$ potential can generate a sufficiently large GWs amplitude to be detected in future experiments.

Next, we consider an ultraviolet (UV) completion of such an extra $U(1)$ extended SM. A primary candidate for the completion is an $SO(10)$ GUT model, in which the extra $U(1)$ gauge group along with the SM gauge group is embedded, and all the SM fermions and RH neutrinos in each generation are also unified into a single **16** representation of $SO(10)$ (see, for example, a review[46] and references therein). Among several possible paths of symmetry breaking from the $SO(10)$ to the SM gauge group, we consider the following two step breaking. The first breaking $SO(10)$ into $SU(5)\times U(1)$ takes place at a very high scale $M_{\mathrm{SO}(10)}$. As the second step, the $SU(5)$ breaks to the SM gauge group at a scale $M_{\mathrm{SU}(5)} \simeq 10^{16}$ GeV. We show that the parameter set compatible with $SO(10)$ unification can produce a detectable GWs spectrum.[41]

This paper is organized as follows: In the next section, we describe the minimal and non-miminal $U(1)_{B-L}$ model and then derive the resultant GWs spectrum by estimating the latent heat and the transition timescale of the phase transition. In Sect. 3, after we describe the outline for the $SO(10)$ unification of the $U(1)$ extended SM based on the gauge group of $SU(3)_C \times SU(2)_L \times U(1)_Y \times U(1)_X$.

through an intermediate path with the $SU(5) \times U(1)_X$ unification, we compute the GWs spectrum generated by the first-order phase transition of $U(1)_X$ and present the resultant GWs spectrum for various sets of the model parameters. The last section is devoted to our summary.

2. Gravitational waves from $U(1)_{B-L}$ phase transition

After we briefly summarize the properties of GWs produced by a first-order phase transition in the early Universe, we show the amplitude and the spectrum of GWs from the first-order phase transition associated with the spontaneous $U(1)_{B-L}$ gauge symmetry breaking within the minimal Higgs model[39] and a non-minimal Higgs model.[35]

2.1. *Scalar potential parameters related to the GW spectrum*

We consider the following two types of tree-level scalar potential. One is the potential for the minimal model:

$$V_0(\Phi_2) = -M_{\Phi_2}^2 \Phi_2 \Phi_2^\dagger + \frac{1}{2}\lambda_2 (\Phi_2 \Phi_2^\dagger)^2, \tag{1}$$

and the other is a non-minimal form with two Higgs fields:

$$\begin{aligned} V_0(\Phi_1, \Phi_2) = {} & \frac{1}{2}\lambda_1 (\Phi_1 \Phi_1^\dagger)^2 + \frac{1}{2}\lambda_2 (\Phi_2 \Phi_2^\dagger)^2 + \lambda_3 \Phi_1 \Phi_1^\dagger (\Phi_2 \Phi_2^\dagger) \\ & + M_{\Phi_1}^2 \Phi_1 \Phi_1^\dagger - M_{\Phi_2}^2 \Phi_2 \Phi_2^\dagger - A(\Phi_1 \Phi_1 \Phi_2^\dagger + \Phi_1^\dagger \Phi_1^\dagger \Phi_2). \end{aligned} \tag{2}$$

The subscript i of Φ_i stands for the $B - L$ charge of each Φ_i field. Here, M_{Φ_i}, λ_i, and A are real positive parameters. We omit the SM Higgs field part and its interaction terms because of those little importance. The Yukawa interactions of N_R are given by

$$\mathcal{L}_{Yukawa} \supset -\sum_{i=1}^{3}\sum_{j=1}^{3} Y_D^{ij} \overline{l_L^i} H N_R^j - \frac{1}{2}\sum_{k=1}^{3} Y_{N^k} \Phi_2 \overline{N_R^{k\,C}} N_R^k + \text{H.c.}, \tag{3}$$

where the first term is the neutrino Dirac Yukawa coupling, and the second is the Majorana Yukawa couplings. Once the Higgs field Φ_2 develops a nonzero VEV, the $U(1)$ gauge symmetry is broken and the Majorana mass terms of the RH neutrinos and the mass of the extra gauge boson are generated. After the electroweak symmetry breaking, tiny neutrino masses are generated through the seesaw mechanism. The experimental bounds on the extra gauge boson are derived as the LEP constraint $m_{Z'}/g_{B-L} \gtrsim 6$ TeV[47,48] and the LHC Run 2 constraints $m_{Z'} \gtrsim 3.9$ TeV[49–52] for $g_{B-L} \simeq 0.7$.

In order to realize a first-order phase transition, the magnitude of the cubic term in the scalar potential

$$V(\varphi) \sim m^2 \varphi^2 - E\varphi^3 + \lambda\varphi^4, \tag{4}$$

is crucial, where φ is defined as $\Phi = \varphi/\sqrt{2}$. There are two possibilities of the origin of the cubic term: One case is that the effective cubic term is induced as loop thermal corrections, and the other is that the term exists in the tree level potential. The cases (1) and (2) above are representative samples of each case. The former corresponds to the case of thermal correction and the later does to the tree level model respectively.

In calculation of the phase transition, we include one-loop corrections to the scalar potential for zero temperature $\Delta V_{1-\text{loop}}(\varphi)$ and that for a finite temperature T given by

$$\Delta V_T(\varphi) = \sum_s g_s \frac{T^4}{2\pi^2} J_B(m_s^2(\varphi)/T^2) - \sum_f g_f \frac{T^4}{2\pi^2} J_F(m_f^2(\varphi)/T^2) + \sum_v g_v \frac{T^4}{2\pi^2} J_B(m_v^2(\varphi)/T^2), \tag{5}$$

where g_i, with $i = s$ (scalars), f (fermions) and v (vectors) denotes the number of internal degrees of freedom, $m_i(\varphi)$ are φ dependent masses for i-th particles. $J_{B(F)}$ is an auxiliary function in thermal corrections.[53,54] As is well known, $J_B(x^2)$ is expressed as

$$J_B(x^2) \simeq -\frac{\pi^4}{45} + \frac{\pi^2}{12}x^2 - \frac{\pi}{6}(x^2)^{3/2} + ..., \tag{6}$$

at the high temperature expansion. The third term induces the effective cubic term that could make the transition of the first order even if the tree level potential does not contain a cubic term as in the potential (1).

For our numerical calculations, we have implemented our models into the public code `CosmoTransitions`,[55] where both zero- and finite-temperature one-loop effective potentials with the corrections for resummation,

$$V_{\text{eff}}(\varphi, T) = V_0(\varphi) + \Delta V_{1-\text{loop}}(\varphi) + \Delta V_T(\varphi, T), \tag{7}$$

have been calculated in the $\overline{\text{MS}}$ renormalization scheme. Here, as a caveat, we note that there is a long-standing open problem of gauge dependence on the use of the effective Higgs potential. Our results are also subjects of this issue[56,57] and should be regarded as a reference value.

By using `CosmoTransitions`, we find the bounce solution of φ and the bounce action for the transition, the bubble nucleation temperature $T_\star$,[58] and the latent heat energy density ϵ in the radiation dominated Universe. With the bounce solution and action, we obtain the dimensionless transition timescale

$$\frac{\beta}{H_\star} \simeq T\frac{dS}{dT}\bigg|_{T_\star} = T\frac{d(S_E^3/T)}{dT}\bigg|_{T_\star}, \tag{8}$$

with

$$\beta \equiv -\frac{dS}{dt}\bigg|_{t_\star}, \tag{9}$$

from the bounce action[10] in the four-dimensional Minkowski space S and in the three-dimensional Euclidean space S_E^3. Here, $t_\star$ is the bubble nucleation time.

2.2. *The GW spectrum*

There are three main processes and mechanisms of GWs production: bubble collisions, turbulence and sound waves after bubble collisions. The resulting spectrum of the generated background GWs is given by

$$\Omega_{GW}(f) = \Omega_{GW}^{\rm coll}(f) + \Omega_{GW}^{\rm sw}(f) + \Omega_{GW}^{\rm turb}(f), \tag{10}$$

in terms of the density parameter Ω_{GW}. The three terms on the right side indicate the GW produced by bubble collisions, sound waves, and turbulence, respectively. We adopt the fitting formula of spectrum commonly adopted in literature[4–6] as well as our papers.[35,39,41]

We only show predicted GWs spectra for our benchmark points of the minimal Higgs model (1) with expected sensitivities of various future experiments,[59] while one may find the similar spectrum of GWs in non-minimal model.[35] One benchmark point $(g_{B-L}, v_2, \lambda_2) = (0.44, 4\,\text{TeV}, 1.5\times10^{-4})$ is shown by the green curve, while the other $(g_{B-L}, v_2, \lambda_2) = (0.46, 3.8\times10^3\,\text{TeV}, 4.0\times10^{-4})$ is shown by the red curve in Fig. 1. The green curve point is similar to the lowest energy case satisfying the LHC limit. An approximate relationship can be seen that $f_{\rm peak}$ is proportional to the VEV of Φ_2, v_2. Next, we discuss the resulting GWs spectrum gauge coupling dependency. The GWs spectrum for various values of the $B-L$ gauge coupling constant for the fixed value of $v_2 = 10$ TeV and $\lambda_2 = 0.002$ is shown in Fig. 2. We have found a mild dependence for the frequency but the amplitude is quite sensitive. The largest amplitude is obtained for $0.35 \lesssim g_{B-L} \lesssim 0.4$. Here, we note that the GWs amplitude in Figs. 1 and 2 have been re-evaluated with taking the suppression effect due to the short-lasting sonic wave[60–64] into account and smaller than previous estimations.[39]

3. UV completion by SO(10)

3.1. *From $U(1)_{B-L}$ to $U(1)_X$*

We consider the UV completion of the $U(1)$ extended SM by $SO(10)$ GUT via the intermediate step of $SU(5)\times U(1)_X$ unification. To realize this partial unification, we generalize $U(1)_{B-L}$ of the minimal $B-L$ model to $U(1)_X$, under which the charge of an SM field is defined as a linear combination of its hyper-charge and $B-L$ charge, $q_X = Yx + Q_{B-L}$, with x being a real constant.[65,66] The particle content of this model is listed in Table 1. Except for the introduction of the new parameter x, the model properties are quite similar to those of the minimal $B-L$ model, which is realized as the special case of $x=0$. Another limit $|x| \gg 1$ is called a "hyper-charge oriented" case.[67–69]

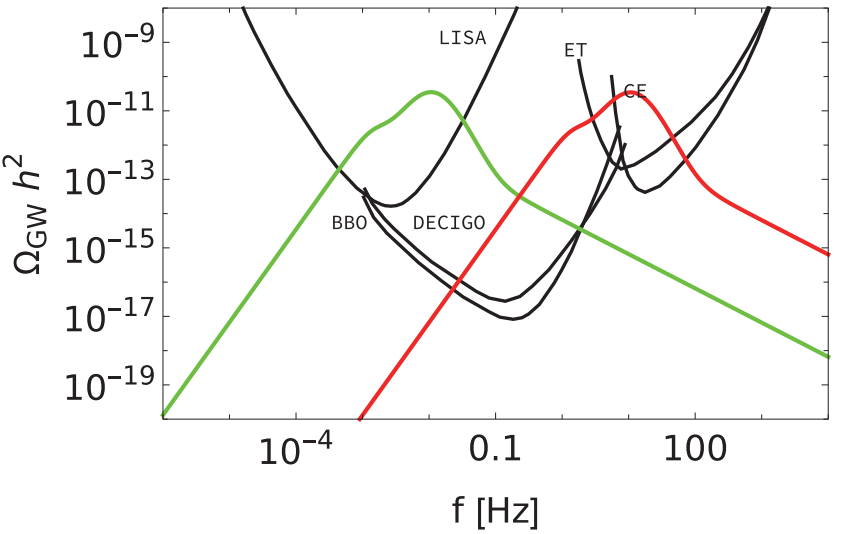

Fig. 1. The predicted GWs spectra for two benchmark points are shown. The expected sensitivities of each indicated experiments[59] are shown by black solid curves.

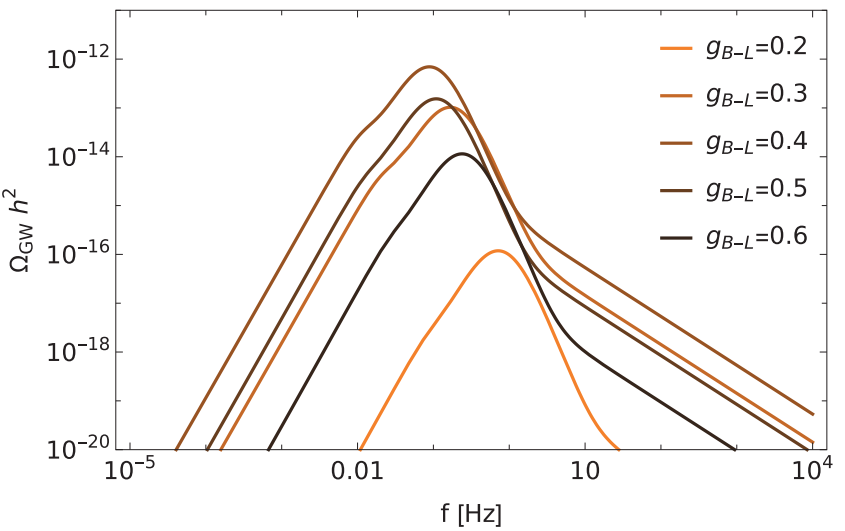

Fig. 2. The predicted GWs spectrum for various values of g_{B-L} for $v_2 = 10$ TeV and $\lambda_2 = 0.002$.

3.2. $SU(5) \times U(1)_X$ *unification*

3.2.1. $SU(5) \times U(1)_X$ *embedding*

We now consider the embedding,

$$SU(5) \times U(1)_X \supset SU(3)_C \times SU(2)_L \times U(1)_Y \times U(1)_X. \tag{11}$$

Table 1. The particle content of the minimal $U(1)_X$ model. In addition to the SM particle content ($i = 1, 2, 3$), three RH neutrinos N_R^i ($i = 1, 2, 3$) and one $U(1)_X$ Higgs field Φ_2 are introduced.

	$SU(3)_C$	$SU(2)_L$	$U(1)_Y$	$U(1)_X$
q_L^i	**3**	**2**	$\frac{1}{6}$	$\frac{1}{6}x + \frac{1}{3}$
u_R^i	**3**	**1**	$\frac{2}{3}$	$\frac{2}{3}x + \frac{1}{3}$
d_R^i	**3**	**1**	$-\frac{1}{3}$	$-\frac{1}{3}x + \frac{1}{3}$
l_L^i	**1**	**2**	$-\frac{1}{2}$	$-\frac{1}{2}x - 1$
e_R^i	**1**	**1**	-1	$-x - 1$
N_R^i	**1**	**1**	0	-1
H	**1**	**2**	$-\frac{1}{2}$	$-\frac{1}{2}x$
Φ_2	**1**	**1**	0	-2

As in the standard $SU(5)$ GUT,[70] the charge conjugation of RH down quarks and left-handed leptons are embedded in $\mathbf{5}^*$ representation of $SU(5)$, while left-handed quarks, the charge conjugation of RH up quarks, and the charge conjugation of RH charged leptons are embedded in **10** representation:

$$\mathbf{5}^* \supset d_R^{iC} \oplus \ell_L^i, \qquad \mathbf{10} \supset q_L^i \oplus u_R^{iC} \oplus \ell_R^{iC}. \tag{12}$$

This is possible for $x = -4/5$ and hence the $SU(5)$ unification leads to a quantization of $U(1)_X$ charge.[71]

3.2.2. *Gauge coupling unification to $SU(5)$*

A simple setup to achieve the unification of the three SM gauge couplings is to introduce two pairs of vector-like quarks ($Q + \bar{Q}$ and $D + \bar{D}$) with TeV scale masses, M_Q and M_D, respectively. Their representations are listed in Table 2. In the presence of the exotic quarks, the SM gauge couplings are successfully unified at $M_{\mathrm{SU(5)}} \simeq 10^{16}$ GeV.[72–78] This unification scale corresponds to the proton lifetime of $\tau_p \simeq 10^{38}$ yr, which is much longer than the current experimental lower limit of $\tau(p \to \pi^0 e^+) \simeq 10^{34}$ yr reported by the Super-Kamiokande collaboration.[79]

Table 2. Representations of the vector-like quarks.

	$SU(3)_C$	$SU(2)_L$	$U(1)_Y$	$U(1)_X$
Q	**3**	**2**	$\frac{1}{6}$	$\frac{1}{5}$
$\bar{Q}$	$\mathbf{3}^*$	**2**	$-\frac{1}{6}$	$-\frac{1}{5}$
D	**3**	**1**	$-\frac{1}{3}$	$\frac{3}{5}$
$\bar{D}$	$\mathbf{3}^*$	**1**	$\frac{1}{3}$	$-\frac{3}{5}$

We show the gauge coupling unification by solving the renormalization group (RG) equations of the SM gauge couplings including the contributions of exotic quarks Q and D also into the beta function coefficients. Our results are shown in Fig. 3. We set the vector-like quark masses to be $M_Q = M_D = 1.5$ TeV, which

satisfy the latest LHC bounds.[80,81] We find that three SM gauge couplings are successfully unified at $M_{\rm SU(5)} \simeq 2.24 \times 10^{16}$ GeV. We will discuss the RG evolution for g_χ in the next subsection.

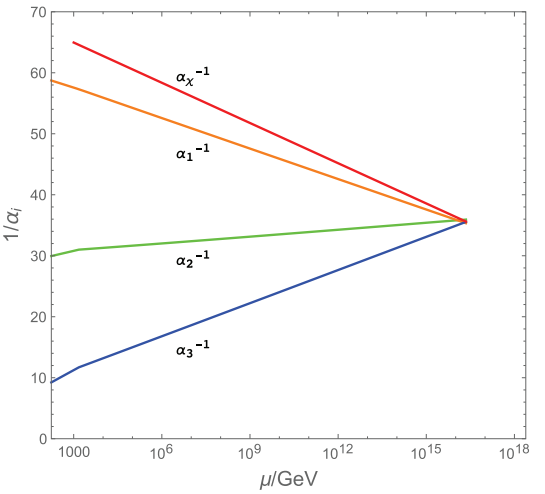

Fig. 3. The RG evolution of the gauge couplings of the $U(1)$ extended SM with the vector-like quarks. Three SM gauge couplings are unified at $M_{\rm SU(5)} \simeq 2.24 \times 10^{16}$ GeV. The results for the case of $M_{\rm SU(5)} = M_{\rm SO(10)}$.

3.3. *SO*(10) *unification*

The $SU(5) \times U(1)_X$ can be embedded into $SO(10)$. The decomposition of several $SO(10)$ multiplets to $SU(5) \times U(1)_X$ is given by[82]:

$$
\begin{aligned}
SO(10) &\supset SU(5) \times U(1)_X \\
\mathbf{10} &= \mathbf{5}(-2/5) + \mathbf{5}^*(2/5), \\
\mathbf{16} &= \mathbf{1}(1) + \mathbf{5}^*(-3/5) + \mathbf{10}(1/5), \\
\mathbf{45} &= \mathbf{1}(0) + \mathbf{10}(-4/5) + \mathbf{10}^*(4/5) + \mathbf{24}(0), \\
\mathbf{126} &= \mathbf{1}(2) + \mathbf{5}^*(2/5) + \mathbf{10}(6/5) + \mathbf{15}^*(-6/5) + \mathbf{45}(-2/5) + \mathbf{50}^*(2/5).
\end{aligned}
$$

The SM fermions and RH neutrinos are embedded in **16** representation. The SM Higgs doublet (H) is embedded in **10** representation,[a] while the $U(1)_X$ Higgs field (Φ_2) is in **126** representation. Exotic quarks $D + \bar{D}$ in $(\mathbf{5}, 3/5) + (\mathbf{5}^*, -3/5)$ are embedded in $\mathbf{16}^* + \mathbf{16}$ multiplets in the $SO(10)$ GUT, while $Q + \bar{Q}$ in $(\mathbf{10}, 1/5) + (\mathbf{10}^*, -1/5)$ are embedded in $\mathbf{16} + \mathbf{16}^*$ multiplets. Similarly to the embedding of

[a]To be precise, for deriving realistic SM fermion mass matrices, the SM Higgs doublet is identified with a linear combination of $SU(2)_L$ doublets in **10** and **126** representations. See Eq. (15) for the Yukawa coupling in the $SO(10)$ GUT.

$U(1)_Y$ into $SU(5)$, the $SO(10)$ GUT normalization of $U(1)_X$ is given by

$$g_X = \sqrt{\frac{5}{8}} g_\chi, \qquad Q_\chi = \sqrt{\frac{5}{8}} Q_X. \tag{13}$$

For simplicity, we assume the $SO(10)$ symmetry breaking to the $U(1)_X$ extended SM by non-zero vacuum expectation values (VEVs) of $\langle \mathbf{1}(0) \rangle$ and $\langle \mathbf{24}(0) \rangle$ in a **45**-representation Higgs field:

$$SO(10) \underset{\langle \mathbf{1}(0) \rangle}{\longrightarrow} SU(5) \times U(1)_X \underset{\langle \mathbf{24}(0) \rangle}{\longrightarrow} SU(3)_C \times SU(2)_L \times U(1)_Y \times U(1)_X. \tag{14}$$

The final $U(1)_X$ breaking can be realized by a non-zero VEV of $\Phi_2^\dagger = \mathbf{1}(2) \subset \mathbf{126}$ Higgs field. The Yukawa interactions for the SM fermions are given by

$$\mathcal{L}_{\text{Yukawa}} \supset Y_{10} \mathbf{16}_f \mathbf{16}_f \mathbf{10}_H + Y_{126} \mathbf{16}_f \mathbf{16}_f \mathbf{126}_H^\dagger, \tag{15}$$

where $\mathbf{16}_f$ is a fermion multiplet (the generation index is suppressed), and $\mathbf{10}_H$ and $\mathbf{126}_H$ are Higgs fields. Referring the above decomposition, one can see that the VEV of $\mathbf{1}(2) \subset \mathbf{126}$ Higgs breaks the $U(1)_X$ symmetry and generates Majorana masses of RH neutrinos in $\mathbf{16}_f$ through the Yukawa coupling Y_{126} in Eq. (15).

3.4. *Gauge coupling unification to SO(10)*

After the successful unification of the SM gauge groups to $SU(5)$ at $M_{\text{SU(5)}}$ we consider the unification of $SU(5) \times U(1)_\chi \to SO(10)$ at $M_{\text{SO(10)}}$. The simplest case is $M_{\text{SU(5)}} = M_{\text{SO(10)}}$, then the running coupling $g_\chi(\mu)$ is determined so as to satisfy the unification condition $g_\chi(M_{\text{SU(5)}}) = g_i(M_{\text{SU(5)}})$ $(i = 1, 2, 3)$. The result is shown in the left-handed panel of Fig. 3. For a case of $M_{\text{SU(5)}} < M_{\text{SO(10)}}$, we need to solve the RG evolution of g_5 and g_χ in the energy range of $M_{\text{SU(5)}} < \mu < M_{\text{SO(10)}}$. We omit discussion of those cases here, however, we have shown that the unification of $SU(5) \times U(1)_\chi$ into $SO(10)$ is possible.

3.5. *The GW spectrum*

First, we show the dependence of the GWs spectrum on the energy scale of symmetry breaking, or equivalently, the VEV (v_2) scale. In Fig. 4 we show the GWs spectrum for different symmetry breaking scales for a fixed value of $\lambda_2 = 6 \times 10^{-4}$. As expected, the peak frequency becomes higher, as the symmetry breaking occurs at higher energies. The black solid curves denote the expected sensitivities of each indicated experiment: LISA, DECIGO, BBO, ET, and Cosmic Explore (CE). The expected sensitivity curves for each experiment were based on one of the latest results.[59]

Next, we study how the $U(1)_X$ Higgs quartic coupling and Yukawa coupling affect the resultant GWs spectrum. As a Yukawa coupling increases, the peak amplitude decreases with the peak frequency increasing. This is because fermion loops generate only thermal mass term and not an effective trilinear term in the thermal

potential (5), which weakens the first order phase transition. Assuming the hierarchy among the Yukawa couplings as $Y_{N_3} \equiv Y_N \gg Y_{N_2}, Y_{N_1}$, for simplicity, we show in Fig. 5 the GWs spectrum for various values of Y_N and λ_2 for $g_\chi = 0.463$ and $v_2 = 1$ PeV.

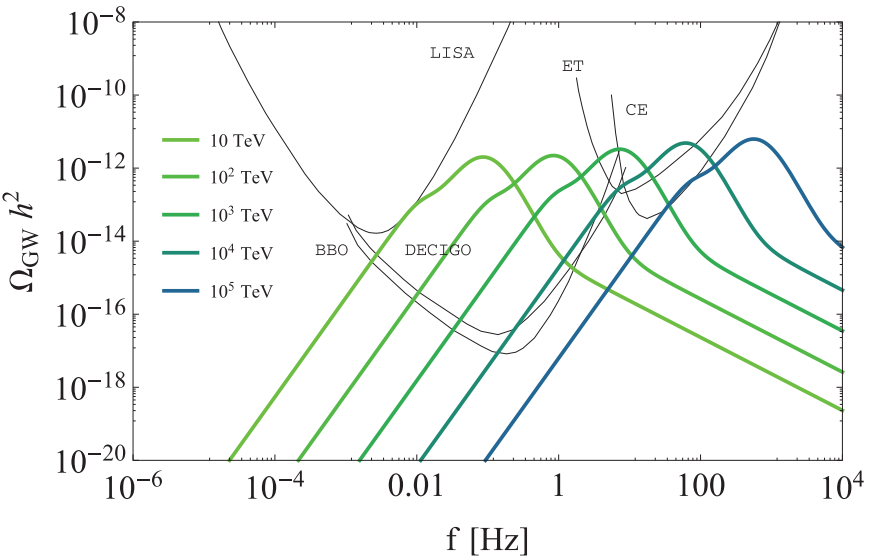

Fig. 4. The predicted GWs spectrum for various symmetry breaking scales for $\lambda_2 = 6 \times 10^{-4}$. The difference of the symmetry breaking scale is indicated by colors as shown in the legends. The expected sensitivities of each indicated experiments[59] are shown by black solid curves.

4. Summary

In this paper, we have considered the $U(1)_X$ extended SM and studied the spectrum of stochastic GWs generated by the first-order phase transition associated with the extra $U(1)_X$ symmetry breaking in the early Universe. This breaking is responsible for the generation of Majorana masses of RH neutrinos and may be surveyed by the GWs spectrum.

We also have shown a UV completion of the $U(1)_X$ extended SM by an $SO(10)$ GUT. We have found that the first-order phase transition triggered by this extra $U(1)$ symmetry breaking can be strong enough to generate GWs with a detectable size of amplitude if the $U(1)_X$ Higgs quartic coupling is small enough and the symmetry breaking scale (the bubble nucleation temperature $T_\star$) is smaller than about 10^5 (10^4) TeV.

We have also clarified the dependence of the resultant GWs spectrum on the RH neutrino Majorana Yukawa couplings, in other words, the mass scale of RH neutrinos. It can be seen as the reduction of the amplitude and the shift of peak

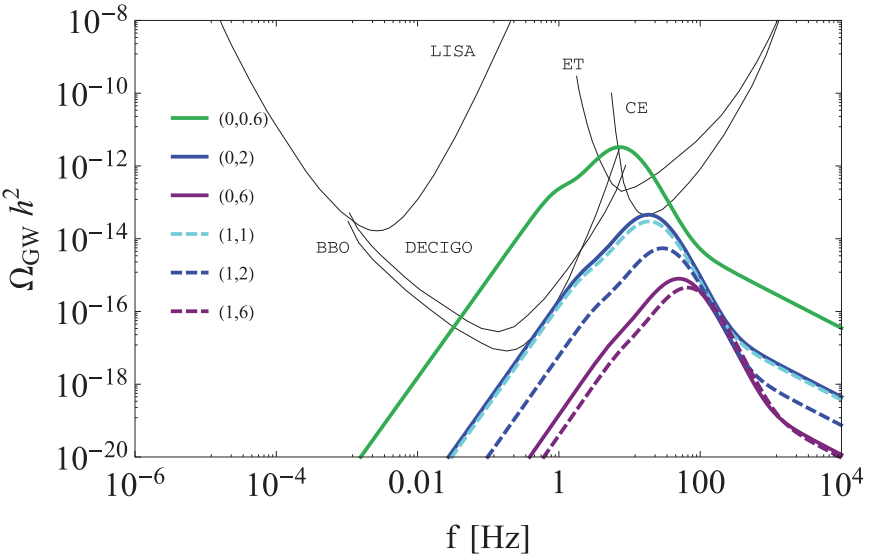

Fig. 5. The predicted GWs spectrum for various values of Y_N and λ_2 for $g_\chi = 0.463$ and $v_2 = 1$ PeV. Parameters in the legend denote $(Y_N, \lambda_2 \times 10^3)$.

frequency of GWs background, which is very similar to the effect of the variation of the $U(1)_X$ Higgs quartic coupling nevertheless.

In this report, we evaluate the performance of the proposed Euro-Asian network (EAN) of gravitational wave (GW) interferometers, which is planned taking into account the location of one of the detectors at the RAS Novosibirsk Scientific Center. EAN is formed by four detectors: VIRGO, KAGRA, LIGO India and Novosibirsk. The efficiency of this configuration is calculated based on typical numerical criteria for wide area networks.[1] One of the key criteria is the accuracy of reconstructing the parameters of GW bursts, which links the calculation of this criterion to a specific class of astrophysical sources. We present results for calculations performed for the chirp signals from the of relativistic binaries inspiral and for signals from rotating collapsing stars. Maximizing the integral criterion we find the optimal orientation of the Novosibirsk detector, which is specified by the angle between the south direction and the bisector of the Michelson arms of the GW interferometer.

Keywords: Gravitational waves; Network of detectors; Binary merger; gravitational collapse

1. Introduction

In September 2015, the first direct registration of a gravitational-wave burst from the merger of a relativistic binary, whose components were evaluated as black holes (BH), took place. The detection of this event was carried out using LIGO detectors.[2] After there were several other similar registrations. A qualitative step was the registration by three detectors (including a similar interferometer VIRGO in Europe) GW170814 burst from the merger of BH binary ($M = 30M_{\odot}$) from the distance of 540 Mps,[3] which allowed to reduce the localization zone of the source on the celestial sphere by an order of magnitude, up to $\sim 60\ deg^2$. A gravitational wave (GW) signal from neutron stars (NS) merger was registered, coinciding with GRB170817A gamma burst (with 1.7 s delay).[4] One of the most recent significant steps is the registration of gravitational waves from the neutron star – black hole binaries coalescence.[5] All these facts allow to claim confidently real occurrence of a new gravitational-wave channel of astrophysical information and heuristic value of multi-messenger astronomy, i.e. strategy of parallel observation of transients on detectors of different physical nature. However, there is still no observation of gravitational waves from supernova as well as significant coincidence between

LIGO/VIGRO data and neutrino detectors like NOvA[6] and IceCube[7] experiments. Gravitational waves from core-collapse supernovae can serve as an important source of information about the processes occurring during a given event.[8]

In this context, we continue the discussion of a European-Asian network (EAN)[9] which consists of four antennas in the northern hemisphere: VIRGO in Italy, KAGRA in Japan, LIGO-India in India and the planned new additional antenna in Novosibirsk. In order to assess the scientific feasibility and efficiency of such a network the calculation of its main characteristics was performed in the approach developed in Refs. 1, 10.

Here we consider two sources of gravitational wave signals: inspiral of a relativistic binary and collapsing stars at the protoneutron star stage which is subjected to rotational instabilities. For both sources we define the optimal orientation angle of possible detector in Novosibirsk by maximizing the integral effiency criteria.

Table 1 shows the coordinates of the detectors in question. The detector orientation angle γ is defined as the angle between the southward direction at the detector location and the bisector of the angle formed by its arms, measured counterclockwise.

Table 1. Detector data; all angles given in degrees.

Detector	Latitude l	Longitude L	Orientation γ
VIRGO	43.6	-10.5	206.5
KAGRA	36.4	-137.3	163.3
LIGO India	19.6	-77.0	254.0
Novosibirsk	55.0	-82.9	to be defined

It's worth noting that in addition to the planning Novosibirsk interferometer, today a project of search for neutrino and gravitational correlations using the OGRAN gravitational detector and the BUST neutrino telescope is being developed in Russia.[11]

2. Criteria of a network

To estimate efficiency of a network of ground based detectors it's necessary to construct power patterns of individual components and the whole network. Here we review the basic information necessary for construction of the pattern and calculation of the criteria.

In the long wavelength approximation (the GW wavelength is much larger than the interferometer arm length L) the detector response can be evaluated as

$$h(t) = \frac{\delta L}{L} = F_+(\theta, \varphi, \psi)h_+(t) + F_\times(\theta, \varphi, \psi)h_\times(t), \tag{1}$$

where $F_+(\theta, \varphi, \psi)$, $F_\times(\theta, \varphi, \psi)$ are the antenna pattern functions for the two polarizations, which are functions of the polar angle θ and the azimuth angle φ of the

spherical coordinate system (XY is the detector plane) and the polarization angle of the GW ψ.

Antenna pattern functions have the following form (in the coordinate frame, which basis vectors, coincide with the direction of the detector arms):

$$F_+ = \frac{1}{2}(1+\cos^2\theta)\cos 2\varphi\cos 2\psi - \cos\theta\sin 2\varphi\sin 2\psi, \tag{2}$$

$$F_\times = \frac{1}{2}(1+\cos^2\theta)\cos 2\varphi\sin 2\psi + \cos\theta\sin 2\varphi\cos 2\psi. \tag{3}$$

In Ref. 12 it's shown that for a network of N detectors network antenna power pattern P^N:

$$P^N = \sum_{k=1}^{4}(F_{+,k}^2 + F_{\times,k}^2). \tag{4}$$

In order to choose the optimal detector angle in Novosibirsk, we use 3 independent criteria presented in Refs. 1, 10. These three criteria form an integral criterion, which is to be maximized by changing the orientation of the Novosibirsk detector, to find the most effective angle.

2.1. *Polarization criterion I*

Criterion I characterizes ability of the network to assess the polarization of the received GW. Following Ref. 1 we define + and × integral functions for a network of four detectors:

$$F^N = \frac{1}{2}\sqrt{F_1^2 + F_2^2 + F_3^2 + F_4^2}, \tag{5}$$

where N - stands for a network function and $F_1 ... F_4$ all either correspond to the + or × polarization. Obviously F^N depend on the polarization angle of ψ.

Calculation of I is carried out in dominant polarization frame (DPF).[13] In DPF for each point on the celestial sphere $(\alpha;\delta)$ (in equatorial coordinate system point is defined by right ascension $\alpha \in [-\pi;\pi]$ and declination $\delta \in [-\frac{\pi}{2};\frac{\pi}{2}]$) a polarization angle that maximizes the network factor F_+^N and minimizes $F_\times^N$ is chosen. Consequently, for this direction $(\alpha;\delta)$ the condition $F_+^N \geq F_\times^N$ is valid. The condition of approximate equality of factors $F_\times^N$ and F_+^N has to be kept, i.e. $\frac{F_\times^N}{F_+^N} \approx 1$. This means that the gravity detector network will be sensitive to both gravity wave polarizations. It follows that a minimum difference of $\left|F_\times^N - F_+^N\right|$ should be sought for all $(\alpha;\delta)$. This leads to the quantitative formulation of the polarization criterion I[1]:

$$I = \left(\frac{1}{4\pi}\oiint \left|F_+^N(\alpha;\delta) - F_\times^N(\alpha;\delta)\right|^2 d\Omega\right)^{-1/2}, \tag{6}$$

where averaging of $\left|F_\times^N - F_+^N\right|$ over celestial sphere takes place ($d\Omega$ - solid angle). The bigger is I the smaller is the averaged difference $\left|F_\times^N - F_+^N\right|$.

2.2. *Localization criterion D*

Criterion D characterizes the ability of a network to define angular position of a source. In astrometry the problem of a source localization on celestial sphere of a radiation source is solved by a method of triangulation. Triangulation is based on the difference in time between the registration of signals by network detectors. The further apart the detectors are, the greater the time delay is. To maximize the source location accuracy on the celestial sphere, the telescopes should be placed as far apart from each other as possible. According to Ref.,[1] for a network of four detectors D is calculated as the area of the triangle formed by the three detectors in the network, which has the largest area among all possible combinations. If O - the center of the Earth, A, B, C - points where the detectors are located, the area of the corresponding triangle:

$$S_{ABC} = 1/2|[\overrightarrow{AC}, \overrightarrow{AB}]| = 1/2|[\overrightarrow{OC} - \overrightarrow{OA}; \overrightarrow{OB} - \overrightarrow{OA}]|. \tag{7}$$

2.3. *Parameters reconstruction criterion R*

Criterion R characterizes the possibility of reconstruction the parameters of the signal of a known analytical form. According to the Maximum likelihood estimation in the additive Gaussian noise background model, the parameters of the received signal are evaluated by the Rao-Cramer bound. The best possible estimates are obtained using the Fisher information matrix $\Gamma_{\alpha\beta}$[14] in accordance with the formula

$$\Gamma_{\alpha\beta} = Re\left\{4\int_{f_{min}}^{f_{max}} \frac{\overline{\partial_\alpha \tilde{h}(f)}\partial_\beta \tilde{h}(f)}{S_n(f)} df\right\}, \tag{8}$$

where $\tilde{h}(f)$ is the Fourier image of response of the detector, the line above the Fourier image of response represents the complex conjugate, and $S_n(f)$ is the spectral noise density of a single detector. In this paper we assume for simplicity that all detectors have the same noise properties presented in.[15]

Rao-Cramer bound determines the best possible accuracy of parameter P estimation[14]:

$$\delta P^2 = \left(\Gamma_N^{-1}\right)_{PP}, \tag{9}$$

where $\Gamma_N = \sum_{i=1}^{N} \Gamma_i$, i.e. the Fisher information matrix for detector network, is the sum of the corresponding detector matrices constituting the network. The inverse value of the celestial-averaged relative error is a numerical expression of criterion R:

$$R = \left(\frac{1}{4\pi}\oiint \left(\frac{\delta P}{P}\right)^2 d\Omega\right)^{-1/2} = \left\langle \frac{\delta P}{P} \right\rangle^{-1}. \tag{10}$$

Maximization of criterion R leads to the minimum relative error averaged over the celestial sphere in the estimation of the parameter.

2.4. *Integral criterion C*

Integral criterion C is used to compare different configurations of a network:

$$C = \sqrt{\left(\frac{I}{I_{max}}\right)^2 + \left(\frac{D}{D_{max}}\right)^2 + \left(\frac{R}{R_{max}}\right)^2}. \tag{11}$$

Criteria I, D and R together define a three-dimensional space that can be used to define a point which describes a particular configuration. Maximization of C by orientation angle of the detector in Novosibirsk gives the optimal orientation angle and leads to values $I(\gamma_{Nsk}^{max}) = I_{max}, D(\gamma_{Nsk}^{max}) = D_{max}$ and $R(\gamma_{Nsk}^{max}) = R_{max}$ (from the definition it's clear $C_{max} = 1$).

3. Sources

3.1. *Binary inspiral*

As a first typical source of gravitational radiation we consider inspiral of a relativistic binary. For our purposes a rather simplified Newtonian form of gravitational chirp signal, which does not take into account post-Newtonian corrections is sufficient[16]:

$$h(t) = \frac{4}{d_L}\sqrt{F_+^2 + F_\times^2}\frac{G^{5/3}}{c^4}\mathcal{M}^{5/3}(\pi f)^{2/3} cos\left(\Phi + \Psi\right), \tag{12}$$

$$\mathcal{M} = \mu^{3/5} M^{2/5}, \tag{13}$$

$$\Phi = -2\left(\frac{c^3(T-t)}{5GM}\right)^{5/8}, \tag{14}$$

$$f = \frac{1}{\pi M}\left[\frac{5}{256}\frac{c^5 M}{G(T-t)}\right]^{3/8}, \tag{15}$$

where $\mathcal{M}$ is the chirp mass of a system, d_L is the distance to the source, Φ is the phase, f is the frequency, Ψ is the initial phase, M and μ is the total and reduced masses of the binary system, T is the moment of coalescence.

3.2. *Collapsing star*

As a second source of gravitational radiation we consider a core-collapse supernovae. During the core-collapse there exist many mechanisms of gravitational waves radiation on different stages of the process.[17] As Fisher matrix approach (8) requires analytical form of the signal we have considered gravitational waves from long-lived rotational instabilities of a proto-neutron star. If the key result of this instabilities is bar deformation that the radiation can be simulated by radiation from a rotating cylinder (axis of rotation is a bisector of the cylinder axis) with a Gaussian exponent which is introduced phenomenologically to take into account finiteness of

the signal:

$$h(t) = \sqrt{F_+^2 + F_\times^2}\frac{GM\omega^2 L^2}{3c^4 r}(1-3\varepsilon^2)e^{-\frac{4(t-t_0)^2}{t_0^2}}cos(2\omega t+\phi), \tag{16}$$

$$\phi = \pi + \tan^{-1}\frac{F_+}{F_\times}, \tag{17}$$

where G is Newtonian constant of gravitation, c – speed of light, M – mass of the source, L – length of the cylinder, R – radius of the cylinder, ω – source angular frequency, t_0 – characteristic signal length and parameter $\varepsilon = \frac{R}{L}$ characterizes the degree of deformation and is used for calculation of criterion R (10). Gravitational radiation carries away energy from the system so ω decreases over time. However for typical values of source parameters[17] $\omega = 2\pi \times 700$ rad/s, $L = 20$ km, $R = 5$ km, $M = M_\odot$ and $t_0 = 1$ s calculation of gravitational waves luminosity via Einstein's formula[18]:

$$L_{GW} = \frac{G}{5c^5}\left\langle \sum_{j,k=1}^{3} \dddot{Q}_{jk}\left(t-\frac{r}{c}\right)\dddot{Q}_{jk}\left(t-\frac{r}{c}\right)\right\rangle, \tag{18}$$

where Q_{jk} – reduced quadrupole moment and dot denotes time derivative, leads to $\frac{\Delta\omega}{\omega} \sim 10^{-7}$, so we consider ω to be constant.

4. Numerical results and conclusions

To define the optimal orientation angle of possible Novosibirsk detector for the to sources in question we maximize the integral criterion C (11). We have chosen the following typical values for the first source parameters: a binary neutron star with masses of $1.4M_\odot$, without spins, located at a distance of 1 Gpc from the Earth and with an orbital plane perpendicular to the line-of-sight. The results of numerical integration are presented in Figure 1. Criterion D in our approximation does not depend on the orientation angle of the detector in Novosibirsk. The most sensitive to changes in orientation angle is criterion I. The maximum value of integral criterion C is achieved at $\gamma_{Nsk}^{max} = 13^\circ$.

In the case of gravitational collapse the strain $h(t)$ is expected to be several orders of magnitude less than for binary coalescence ($h \sim 10^{-22} - 10^{-20}$ at 10 kpc) so we can't assume isotropic distribution of sources over the celestial sphere. Instead we integrate over the Milky Way disk (neglecting the fact that the sensitivity may be sufficient for detection of the signal from several nearby galaxies). Due to rotation of the Earth antenna pattern functions F_+ and $F_\times$ depend on time (and consequently $P = P(t)$, $\phi = \phi(t)$) thus we average functions of time over 24 hours which also makes analytical calculation of Fourier image $\tilde{h}(f)$ in (8) possible. The parameters of a source are those ones from Section 3.2. The calculation results are shown in Figure 2. Again I is again the most sensitive criterion to changes of orientation angle. The maximum value of integral criterion C is achieved at $\gamma_{Nsk}^{max} = 40^\circ$.

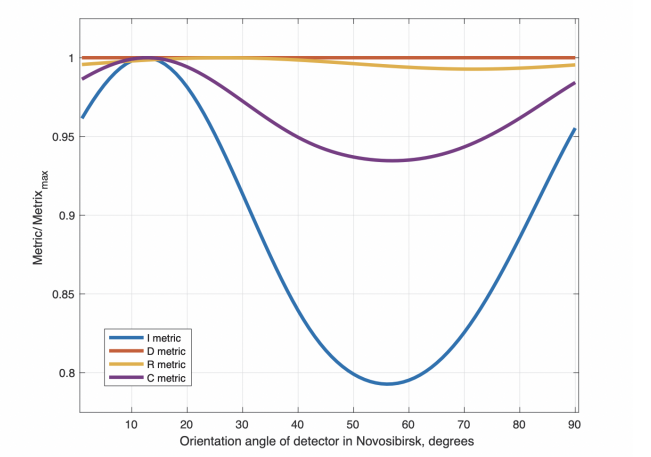

Fig. 1. Dependence of all criteria on orientation angle of detector in Novosibirsk for binary inspiral.

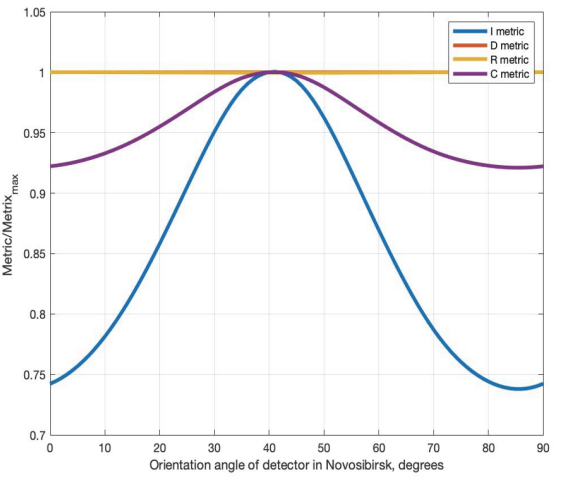

Fig. 2. Dependence of all criteria on orientation angle of detector in Novosibirsk for gravitational collapse.

The final choice of the orientation depends on the most topical problems at the time of construction of the detector in Novosibirsk. To conclude we notice that the choice of the source is a limitation of this work, because more significant physics is encrypted in a more complex structure of the signal from the core collapse, but such signals are model-dependent and do not have an analytical form (e.g.[19]), which does not allow using them within the framework of this approach.

The obtained result shows that in one specific network it is impossible to indicate the orientation of the interferometer in Novosibirsk, which would be optimal both

for GW signals from the coalescence of relativistic binaries and for signals from collapses. This is despite the fact that the collapse model with the stage of rotating cylindrical bar instability is closest to the picture of a merging bynaries at the inspiral stage. At the moment, it is possible to recommend the choice of an averaged orientation with an appropriate estimate of the loss in the accuracy of estimating the parameters of the received signals.

Acknowledgments

Core-collapse supernovae produce copious low-energy neutrinos and are also predicted to radiate gravitational waves. These two messengers can give us information regarding the explosion mechanism. The gravitational wave detection from these events are still elusive even with the already advanced detectors. Here we give a concise and timely introduction to a new method that combines triggers from GW and neutrino observatories; more details shall be given in a forthcoming paper.[1]

Keywords: Multimessenger, supernova, core-collapse, low-energy neutrino, gravitational wave.

1. Introduction

Core-collapse supernovae (CCSNe) are expected to produce multimessenger signals such as neutrinos, gravitational waves (GWs), as well as multi-wavelength electromagnetic waves.[2,3] Low-energy neutrinos (LENs) are expected to be produced by

these events, with the average energy $\sim$ 10 MeV and these LENs are from the majority of the total energy budget ($\sim 10^{53}$ erg) of the CCSNe.

LENs from a CCSN have been successfully detected with the observation of SN1987A in Large Magellanic Cloud by Kamiokande-II,[4] IMB,[5] and Baksan.[6] Today, there are several LEN detectors waiting for these astrophysical events such as Super-Kamiokande[7] (Super-K), LVD,[8] KamLAND,[9] and IceCube[10] with the horizon up to the edge of our galaxy and beyond. These detectors are in fact in a multi-detector collaboration for this effort to produce low-latency alerts under SuperNova Early Warning System (SNEWS).[11,12]

Moreover, the era of multimessenger astronomy involving GWs has just begun with the detection of the binary neutron star merger.[13] Recently, GW search has been in the phase of O3 data taking, which is done by LIGO[14] detectors (4-km arm in Hanford and Livingston USA), Virgo[15] detector (3-km arm in Cascina Italy), and KAGRA[16] (3-km arm in Gifu Prefecture, Japan in the latest period of O3). In total, the GW science data taking has been done for 3 observing runs (O1, O2, and O3) from 2015 to 2020, and currently the detectors undergo improvements in order to be more sensitive for O4 (expected in August 2022). CCSNe are expected to produce GW signals with broad physical processes.[17–20] Detecting GWs from these sources will enable us to study the physical processes. As we will see later on, the detection capability of GWs could be improved by multimessenger search involving LENs.

Here, we provide a timely description of a strategy to combine GWs and LENs for a multimessenger search following the chart in Fig. 1. More details discussion will be given in a forthcoming paper,[1] which has just been accepted by JCAP. This method is based on our previous works.[21,22] We construct a time-coincident strategy and test it with the simulated signals for both GW and LEN data.

In our strategy, we use the `coherent WaveBurst` (cWB) pipeline[23–26] for GW data analysis from simulations. This is a model-agnostic algorithm pipeline that is used to search GWs from CCSNe.[27] Moreover, we also simulate LEN signals arriving in several neutrino detectors and analyse them[a]. At this stage, we use a new approach (introduced in[22]) for neutrino analysis in order to exploit the temporal behaviour of CCSNe. In the next step, we perform a temporal-coincidence analysis between the two messengers. Different messenger data are analysed separately and then combined together for possible GW-LEN signals. This could be interesting for online networks such as SNEWS or offline search for sub-threshold signals.

This paper is organised as follows. In Sec. 2, we discuss the emission models for each messenger. Then, in Sec. 3, the data and analysis by our strategy will be presented. In the end, we show the implementation of our strategy in Sec. 4.

[a]Note that we employ no detailed neutrino-detector simulation.

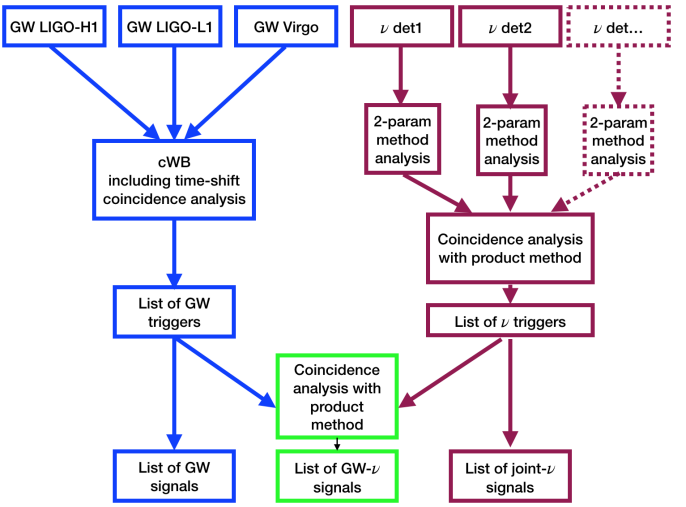

Fig. 1. The schematic view of the multimessenger GW-LEN strategy.

2. Messengers from Core-Collapse Supernovae

A CCSN is expected to produce a $O(10\,\mathrm{ms} - 1\,\mathrm{s})$ GW burst and an impulsive $O(10 - 30\,\mathrm{s})$ emission of $O(10\,\mathrm{MeV})$ LENs[28b], which highly depend on the CCSN initial conditions: progenitor mass, rotation, etc. Thus, it would be ideal to perform a simultaneous GW-LEN analysis from *the same numerical simulation*. Unfortunately, no simultaneous GW-LEN numerical simulations have provided successful CCSN explosion, or if there are, the simulations can only provide both signals for the first half of a second, until the explosion. Meanwhile, the LEN emission duration is expected to last about 10 seconds. Therefore, we combine the currently available GW signals and LEN signals from different simulations with similar progenitor masses, and handle them as if they are from the simultaneous simulation.

2.1. *Gravitational Wave Emission*

We provide the detail of our GW waveforms in Tab. 1. We use the GW signals from the 3D neutrino-radiation hydrodynamics simulations of Radice *et al.*[30] (named as "Rad") with the various zero age main sequence masses in order to have the successful explosions from the low-mass and the failed explosions from the high-mass. Besides, we also take into account models with rapid rotation and high magnetic field which produce much stronger GWs. In this case, we take GW waveforms from two simulations: the Dimmelmeier[31] ("Dim") and the Scheidegger[32] ("Sch"). The stellar progenitors of Dim and Sch have strong rotation and magnetic field. These constraints make the models less favourable to happen than the neutrino-radiation

[b]These signals could also be emitted by "failed" SNe.[29]

mechanism.[27,28,33] Nevertheless, we would not rule out any models since we have not yet detected any CCSN GWs. Thus, we try to cover as broad as possible the uncertainty band from theoretical predictions: the lower limit is from the Rad model, and the upper limit is from the Dim and the Sch models.

Table 1. Waveforms from the considered CCSN simulations. In the columns: emission type and reference, waveform identifier, waveform abbreviation for this manuscript, progenitor mass, angle-averaged root-sum-squared strain $h_{\rm rss}$, frequency when the GW energy spectrum peaks, and emitted GW energy.

Waveform Family	Waveform Identifier	Abbr.	Mass $M_\odot$	$h_{\rm rss}$ @10 kpc $\left[10^{-22}\,\frac{1}{\sqrt{\rm Hz}}\right]$	$f_{\rm peak}$ [Hz]	$E_{\rm GW}$ $[10^{-9}\,M_\odot c^2]$

2.2. *Low-energy Neutrino Emission*

Similar to the previous emission, we consider two models for the LEN emissions. First, we take the signals from the numerical simulations of Hüdepohl obtained for a progenitor of $11.2M_\odot$; without the collective oscillations,[34] with the time-dependent neutrino luminosities, and average energies. The simulation provides the first 7.5 seconds of the neutrino emission with the analytical extension in order to reach 10 seconds of the signal. The average LEN energies from before collapse up to the simulated 0.5 s after bounce are (c.f. Table 3.4 of Ref.[34]): $\langle E_{\nu_e}\rangle = 13$ MeV, $\langle E_{\bar\nu_e}\rangle = 15$ MeV and $\langle E_{\nu_x}\rangle = 14.6$ MeV.

Second, we also use a parametric model for neutrino emission from Pagliaroli *et al.*,[35] focusing on the best-fit emission from SN1987A data and the model provides the average energies of $\langle E_{\nu_e}\rangle = 9$ MeV, $\langle E_{\bar\nu_e}\rangle = 12$ MeV and $\langle E_{\nu_x}\rangle = 16$ MeV. This signal has a temporal structure:

$$F(t,\tau_1,\tau_2) = (1-e^{-t/\tau_1})e^{-t/\tau_2}, \tag{1}$$

where τ_1 and τ_2 are parameters governing the emission, representing the rise and decay timescales of the neutrino signal. The best-fit values on these parameters are ~ 0.1 s and ~ 1 s.[36]

Here, we consider only the main interaction channel for water and scintillator detectors: the inverse beta decay (IBD) $\bar\nu_e + p \to n + e^+$. We also consider standard MSW neutrino oscillations on the flux $\Phi_{\bar\nu_e}$ at the detectors. The flux is an admixture

of the unoscillated flavor fluxes at the source, i.e. $\Phi_{\bar{\nu}_e} = P \cdot \Phi_{\bar{\nu}_e} + (1-P)\Phi_{\bar{\nu}_x}$. Here, P describes the survival probability for the $\bar{\nu}_e$. The value of $P \simeq 0$ is for the Inverted Hierarchy (IH), while $P \simeq 0.7$ is for the Normal Hierarchy (NH). The expected number of IBD events can be seen in Tab. 2 with the reference distance of 10 kpc.

Table 2. Average number of IBD events for a CCSN exploding at 10 kpc for the considered models detected by Super-K,[7] LVD,[8] and KamLAND,[9] with the assumed energy thresholds ($E_{\rm thr}$).

Model (identifier)	Progenitor Mass	Super-K ($E_{\rm thr} = 6.5$ MeV)	LVD ($E_{\rm thr} = 7$ MeV)	KamLAND ($E_{\rm thr} = 1$ MeV)
Pagliaroli[35] (SN1987A)	$25\,M_\odot$	4120	224	255
Hüdepohl[34] (Hud)	$11.2\,M_\odot$	2620	142	154

3. Data and Analysis Strategy

Here, we will discuss the data and analysis for GWs, for LENs, and for a combined multimessenger search. We consider a conservative threshold on global false alarm rate (FAR) of 1/1000 years.

3.1. *Gravitational Wave Analysis*

We employ the cWB[37,38c] algorithm for the GW data analysis, a widely used software in the LIGO-Virgo-KAGRA collaborations; which is also used for the study of CCSN targeted-search.[27,39] The cWB software does not need any waveform templates; it combines coherently the excess energy of the data from the involved GW detectors. A maximum likelihood analysis is used to search for the GW candidates and their parameters. The significance is estimated comparing foreground the detection statistics ρ (of the candidates) with a background distribution from the time-shift procedure. We simulate Gaussian noise with a spectral sensitivity based on the expected Advanced LIGO[40] and Advanced Virgo detectors.[41,42] We simulate ~ 16 days of data and ~ 20 years of background livetime.

Waveforms from the models in Sec. 2.1 have been simulated for several distances: 5, 15, 20, 50, 60, 700 kpc. In terms of sky direction, for the shorter distances (5, 15, 20) we use the Galactic model given in,[43] whereas for the longer (50 and 60 kpc) distances we take fixed directions, either towards the Large or Small Magellanic Clouds, and additionally for the 700 kpc we use the Andromeda direction. We focus

[c]cWB home page, `https://gwburst.gitlab.io/`;
public repositories, `https://gitlab.com/gwburst/public`
documentation, `https://gwburst.gitlab.io/documentation/latest/html/index.html`.

mainly on the 5-60 kpc distances for the multimessenger analysis, while the distance between 60 and 700 kpc are used for the efficiency curve[d]. We inject 1 GW signal per 100 seconds, wide enough for two consecutive waveforms. In terms of sky positions, we apply $\sim$ 2500 different realizations over all the sky direction for each distance and model.

We choose a threshold of 864 per day for GW candidates to be used for our multimessenger analysis, to satisfy the requirement of the combined FAR of 1/1000 years. The efficiency curves for each distance can be seen in Fig. 2 as the ratio of the number of recovered injections ($\mathrm{FAR_{GW}} < 864/\mathrm{day}$) to the $\sim$ 2500 total injections.

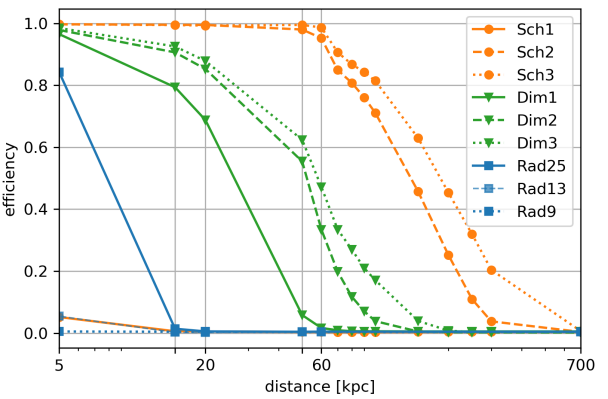

Fig. 2. Efficiency curve of GW search from Advanced LIGO and Advanced Virgo detectors for the various models in Tab. 1, given a FAR threshold of 864/day. Sch1-3 are for the Scheidegger model with different frequency peaks, Dim1-3 are for the Dimmelmeier model with different h_{rss} values, and Rad1-3 are for the Radice model with different progenitor masses

3.2. *Neutrino Analysis: Expanding the Neutrino Detection Horizon*

The standard LEN analysis for CCSNe[44–46] employs a binning in a time series data set with a sliding time window of $w = 20$ seconds. The group of events in a bin is called a *cluster* and the number of events in a cluster is called multiplicity m. We can assume the multiplicity distribution of background events follows a Poisson distribution. For each i-th cluster, we calculate the *imitation frequency* (f^{im}), which is correlated with the significance, defined as,

$$f_i^{\mathrm{im}}(m_i) = N \times \sum_{k=m_i}^{\infty} P(k), \tag{2}$$

[d]For the simulations between 60 and 700 kpc, we use the Andromeda position, though no known astronomical objects are expected around that area.

where $P(k)$ is the Poisson term: the probability in which a cluster of multiplicity k is simply due to the background,

$$P(k) = \frac{(f_{\rm bkg} w)^k e^{-f_{\rm bkg} w}}{k!}, \tag{3}$$

with $N = 8640$ is the total number of bins in one day, calculated from the 10-s overlapping window between two consecutive bins, to tackle the boundary problems. This f^{im} is basically called FAR in the GW community.

From our previous work,[47] we can exploit the temporal behavior of LEN signals with an additional cluster parameter called $\xi_i \equiv \frac{m_i}{\Delta t_i}$, with Δt_i as the i-th cluster duration: the time difference between the last and the first event. Clearly, Δt_i has a maximum value of the bin width itself, which is 20 seconds. A cluster is considered when $m_i \geq 2$, thus $\xi_i \geq 0.1$.

Previous work[47] uses ξ as a cut value. In this work we develop further in order improve the estimation of the imitation frequency. Particularly, it is formulated a new modified **2-parameter** (m and ξ) imitation frequency, called $F^{\rm im}$:

$$F_i^{\rm im}(m_i, \xi_i) = N \times \sum_{k=m_i}^{\infty} P(k, \xi_i), \tag{4}$$

where the term $P(k, \xi_i)$ is the joint probability of a cluster with multiplicity k **and** ξ_i substituting $P(k)$ previously (Eq. 3). Finally, it is convenient to write (see c.f. App. A of[1] and c.f. Sec. 7.1. of[21] for more detail),

$$F_i^{\rm im}(m_i, \xi_i) = N \times \sum_{k=m_i}^{\infty} P(k) \int_{\xi=\xi_i}^{\infty} {\rm PDF}(\xi \geq \xi_i | k) d\xi. \tag{5}$$

Fig. 3 shows the ξ probability density function (PDF) for the Super-K detector (as an example). The black solid line represents the PDF of ξ values due to the background, i.e. PDF($\xi|k$).

We simulate ~ 10 years of background data for each neutrino detector with the assumption that the background frequencies $f_{\rm bkg}$: 0.012 Hz for Super-K,[46] 0.015 Hz for KamLAND,[48] and 0.028 Hz for LVD.[44] Moreover, the CCSN simulated signals (see Sec. 2) are injected into the background data for each detector model (the starting times are simultaneous with the GW injections, with reasonable time delay due to detectors' positions) and for each source distance. These clusters are extracted via the Monte Carlo method and the injection rate is 1 per day.

The clusters are considered signal candidates if their standard $f^{\rm im} \leq 1/{\rm day}$, which has been set in order to reach the global FAR of 1/1000 years. The efficiency for each distance D can be defined as,

$$\eta(D) = \frac{N_{\rm r,s}(D)}{N_{\rm inj,s}(D)}, \tag{6}$$

where $N_{\rm r,s}$ is the number of candidates and $N_{\rm inj,s}$ is the total number of injections. With the recipes up to now, the efficiency curves can be constructed (see Fig. 4).

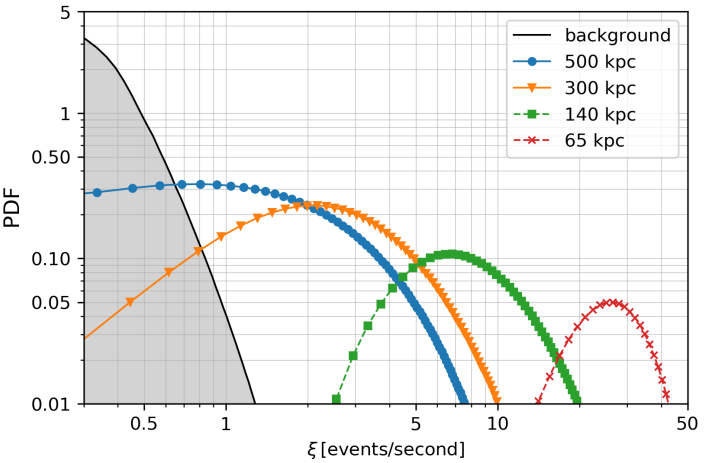

Fig. 3. PDF of ξ values for background (black line) and signal clusters (colored-lines) for different distances in the case of the Super-K detector. Data are from.[47]

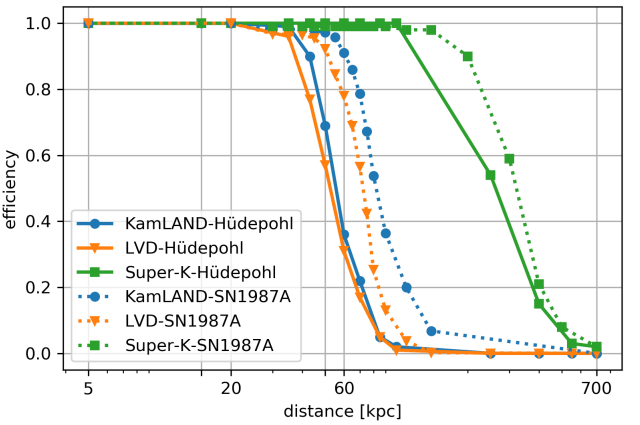

Fig. 4. The efficiency curves of LEN detectors for the Hud (continuous lines) and SN1987A (dashed lines). The imitation frequency threshold is 1/day.

3.3. *Multimessenger Analysis*

The ultimate goal of our work is to construct a multimessenger analysis, combining both LEN and GW data sets (green boxes in Fig. 1). We simply perform a temporal-coincidence analysis between the GW and LEN lists and the statistical significance can be estimated by the combination of its FAR. The joint coincidences are defined as "CCSN candidates".

The $\mathrm{FAR_{GW}}$ is acquired via the time-shifting method (Sec. 3.1) while, the FAR_ν from LEN is obtained by the product method based on SNEWS[11] i.e.,

$$\mathrm{FAR}_\nu = \mathrm{Nd} \times w_\nu^{\mathrm{Nd}-1} \prod_{i=1}^{\mathrm{Nd}} F_i^{\mathrm{im}}, \tag{7}$$

where Nd is the number of LEN detectors, w_ν is the time window of coincidence analysis, and F_i^{im} is the 2-parameter imitation frequency of the clusters.

All in all, the multimessenger $\mathrm{FAR_{glob}}$ from "CCSN candidates" can be written[e],

$$\mathrm{FAR_{glob}} = \mathrm{Net} \times w_c^{\mathrm{Net}-1} \prod_{X=1}^{\mathrm{Net}} \mathrm{FAR}_X, \tag{8}$$

where Net is the number of sub-networks, w_c is the temporal coincidence window between GW and LEN, and FAR_X is the *false-alarm-rate* ($X = \{\nu, \mathrm{GW}\}$). Thus, the *false-alarm-probability* taking into account Poisson statistics can be written,

$$\mathrm{FAP} = 1 - e^{-\mathrm{FAR} \times \mathrm{livetime}}, \tag{9}$$

where "livetime" is the common observing time among the network.

Eq. 8 and 9 are used to compare the performance of our 2-parameter method (Eq. 5) with the standard 1-parameter method (Eq. 2). This performance is discussed as efficiency values, analogous with Eq. 6. For the multimessenger step, we define a "detection" in a network when $\mathrm{FAP} \geq 5\sigma$[f].

4. Results

Here, we discuss the results of our method. First, we mention the single-detector neutrino analysis performance. Next, we show the sub-network of neutrino detectors. Finally, we provide the global network of GW-LEN multimessenger analysis.

4.1. *Improvement of the Single-Detector LEN Analysis*

We work our method on the simulated single-detector data for KamLAND, LVD, and Super-K. To show the improvement, we discuss in the following, as a leading example, the case of the KamLAND detector. We consider a CCSN at 60 kpc with the LEN profile following SN1987A model (the first row of Tab. 2). We perform a 10 years of KamLAND simulated background data and we inject randomly the simulated LENs with the rate of 1/day, thus, 3650 total injections.

All clusters, either due to background or injections, are plotted in Fig. 5 in a ξ vs multiplicity plane. Blue crosses represents the clusters due to injections while the yellow inverted-triangles are due to background. Because of the statistical Poisson fluctuation in the Monte Carlo simulation method, the injection clusters may have

[e] Thorough discussion on the choice of coincidence analysis can be seen in.[21]
[f] $5\sigma \approx 5.7 \times 10^{-7}$

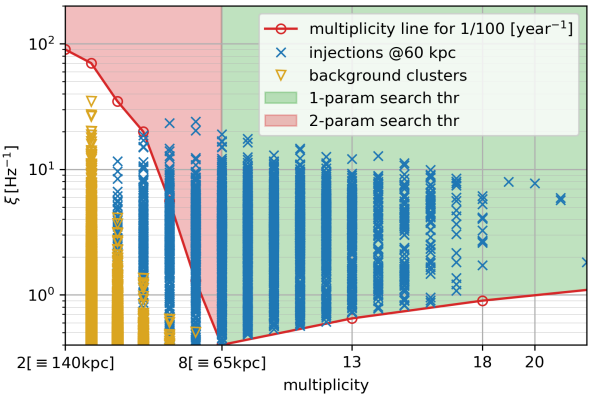

Fig. 5. The ξ-multiplicity map for KamLAND with the simulated background (yellow-triangle) and injection (blue-cross) clusters generated with the SN1987A model at 60 kpc.

various multiplicity values. Besides, background events are also fluctuating in this 20-sec window.

We estimate the associated imitation frequency (or FAR_ν[g]) for each recovered cluster. This imitation frequency in 1-parameter analysis is a function of only the cluster multiplicity via Poisson statistics. To satisfy the SNEWS requirement of $\mathrm{FAR}_\nu \leq 1/100$ year, the multiplicity threshold is 8. This means clusters should lie on the green area of Fig. 5 to satisfy the standard 1-parameter requirement. This limit on the multiplicity could be understood as a KamLAND horizon for CCSN search of $\simeq$ 65 kpc with the model based on SN1987A, in fact it is the average multiplicity for this CCSN configuration: $\langle m_i \rangle = 8$.

On the other hand, the imitation frequency of our 2-parameter method requires each cluster to satisfy the requirement of both multiplicity and the ξ value following Eq. 4. That equation gives us the red line in Fig. 5 for $\mathrm{FAR}_\nu = 1/100$ years[h] required for the 2-parameter method. All clusters above the red line pass the 2-parameter method requirement. This also relax the requirement allowing multiplicity lower than 8 as long as a specific ξ value is satisfied. Thus, the red area in Fig. 5 represents the improvement area of our 2-parameter method comparing with the 1-parameter. In addition, it is clear from the figure that all simulated background clusters (yellow triangles) are well below the red threshold line.

Quantitatively, Fig. 5 shows an increase of the detection efficiency with details given in the first row of Tab. 3. The KamLAND efficiency at 60 kpc is improved from 73% by the standard 1-parameter method to 83% by our 2-parameter method. Moreover, we mention also that there are 75198 noise triggers in this data set and none of them have FAR lower than 1/100 years for both methods. The efficiency

[g]As previously stated in Sec. 3.2, the imitation frequency is actually the FAR. So, FAR_ν is imitation frequency for KamLAND data, either f^{im} or F^{im} depending on the context.
[h]The threshold corresponding to the current SNEWS requirement.

increase could also mean we can expand the detection horizon of the detector since the expected multiplicity is proportional to the inverse of squared-distance[i]. The results for KamLAND are representative for all the scenarios we investigated. Similar improvements can be seen for other scenarios (see c.f. App. C of[1]).

4.2. *The LEN Detector Sub-Network*

We apply our method for the sub-network of LEN detectors: KamLAND and LVD, since their efficiency curves are compatible; see Fig. 4. The threshold for LEN detector network is 5σ in FAP_ν (Eq. 9). We compare the efficiencies in the second and third row of Tab. 3.

Table 3. Efficiency (η) comparison between 1-parameter and 2-parameter method for analysis of KamLAND (with the SN1987A model) and KamLAND-LVD (with the Hud model) and for $\mathrm{FAP}_\nu > 5\sigma$.

Analysis	Model	Distance [kpc] $[> 5\sigma]$	$\eta_{1\mathrm{param}}$ $[> 5\sigma]$	$\eta_{2\mathrm{param}}$
KamLAND	SN1987A	60	**2665/3654=72.9%**	**3026/3654=82.8%**
KamLAND-LVD	Hud	50	**47/108=43.5%**	**59/108=54.6%**
KamLAND-LVD	Hud	60	**19/107=17.8%**	**28/107=26.2%**

At a distance of 50 kpc with a $\mathrm{FAR}_\nu \leq 1/100$ years, we can detect 12% and 26% CCSNe for LVD and KamLAND, respectively. Meanwhile, if the detectors are in a network looking for coincidences within w_ν, it is possible to recover $\sim 43\%$ with 5σ threshold. When we start using 2-parameter method taking into account the ξ distribution for each detector, this efficiency grows to $\sim 55\%$.

Analogously, for CCSNe at 60 kpc, the signals with $\mathrm{FAR}_\nu \leq 1/100$ years can be detected only 3% and 7% for LVD and KamLAND. Whereas, as a network this efficiency increases to 18% and to 26% for 1-parameter and 2-parameter method, respectively for 5σ threshold.

In order to quantify the result, we will mention the results for the SN1987A model with a CCSN at 60 kpc recovered by the LVD-KamLAND network. The improvement in efficiency is from 85% to 93%. These results can be compared with first row of Tab. 3 for the single detector analysis.

4.3. *The Multimessenger Network*

In the multimessenger network, the temporal coincidence window is $w_c = 10$ seconds between GW and LEN lists. We use the 5σ threshold to claim a multimessenger

[i]The number of events is basically a flux.

"detection" of injected signals. We focus on emphasizing the improvement of combining GWs and LENs, which means when the detection efficiency of both LEN and GW detectors is less than 100%. In other words, it is to combine detectors with comparable detection efficiencies. The horizon of the GW network is highly influenced by the assumed GW emission model, see Fig. 2. In this case, the Dim2 model (see Tab. 1) has the GW detection horizon comparable with the LVD and KamLAND detectors, which is more or less the Large Magellanic Cloud distance. Thus, we perform the method for the global network of LIGO-Virgo, LVD, and KamLAND. Results for other GW models can be seen in c.f. App. B of.[1]

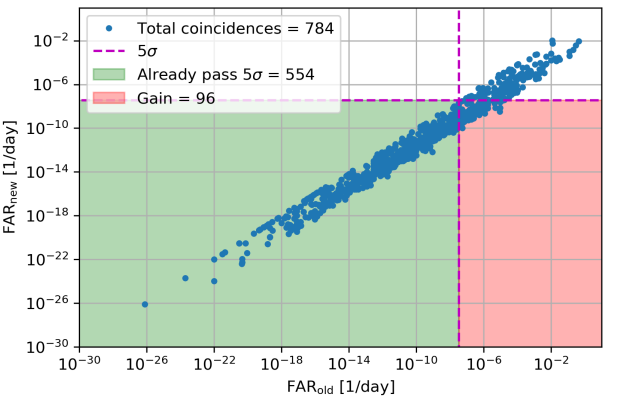

Fig. 6. The joint FAR of GW-LEN candidates obtained with the 2-parameter method ($\mathrm{FAR_{new}}$ y-axis) vs the 1-parameter ($\mathrm{FAR_{old}}$ x-axis) with the **KamLAND** (SN1987A-model) and HLV (Dim2-model) at 60 kpc.

For the coincidence analysis of KamLAND detector with the HLV (Hanford, Livingston, Virgo) GW network, we can see the FAR comparison in Fig. 6 for the case of CCSNe at 60 kpc and with the LENs from SN1987A model and the GW from Dim2 model. The magenta dashed-line is 5σ significance threshold. Either $\mathrm{FAR_{old}}$ or $\mathrm{FAR_{new}}$ values lower than this line mean they pass 5σ. Thus, all clusters (blue dots) lie on the green area are recovered by the 1-parameter method. While, the red area is the improvement: the clusters recovered by the 2-parameter but not by the 1-parameter. The first row of Tab. 4 gives us the efficiency of the 1-parameter and the 2-parameter method. This yields an additional $\sim 12\%$ of signals from the 2-parameter that are discarded by the 1-parameter.

The cWB performs and analyses 2346 GW injections, and out of that, 784 of them have $\mathrm{FAR_{GW}} < 864/\mathrm{day}$. These candidates' significances are far too low to be even taken as *sub-threshold* triggers. Then, temporal coincidence analysis is performed with the input of these GW triggers and the list of LEN clusters. There are 554 coincident candidates that pass 5σ ($\sim 71\%$ of the GW triggers) with the

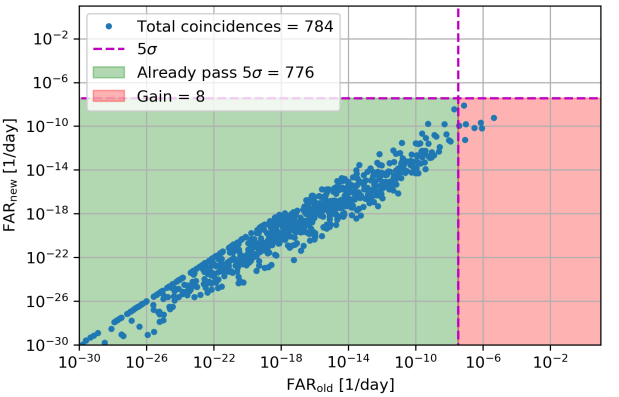

Fig. 7. The joint FAR of GW-LEN candidates obtained with the 2-parameter method ($\mathrm{FAR_{new}}$ y-axis) vs the 1-parameter ($\mathrm{FAR_{old}}$ x-axis) with the **KamLAND-LVD** (SN1987A-model) and HLV (Dim2-model) at 60 kpc.

Table 4. Efficiency comparison of the 1-parameter ($\eta_{1\mathrm{param}}$) and the 2-parameter ($\eta_{2\mathrm{param}}$) method for Fig. 6 (upper row) and 7 (lower row). The first column indicates the specific network of detectors and models. The second column shows the GW results with the threshold on the $\mathrm{FAR_{GW}} < 864$/day). The third and last columns are the efficiency with $> 5\sigma$ significance.

Network & Type of Injections	Recovered $\mathrm{FAR_{GW}} < 864$/d	$\eta_{1\mathrm{param}}$ [$> 5\sigma$]	$\eta_{2\mathrm{param}}$ [$> 5\sigma$]
HLV-KAM (Dim2-SN1987A)	784/2346= 33.4%	554/784= **70.7%**	650/784= **82.9%**
HLV-KAM-LVD (Dim2-SN1987A)	784/2346= 33.4%	776/784= **99.0%**	784/784= **100%**

standard 1-parameter method. However, if we employ the new 2-parameter method, we can get additional 110 recovered signals. This means the efficiency increases to $\sim 83\%$ (the first row of Tab. 4).

We also study further this method involving the LVD detector to be in the triple-detector configuration. We show the result in Fig. 7 and quantitative summary in the second row of Tab. 4. The improvement of our method seems less evident. This is clear due to the fact that the efficiency cannot go beyond the maximum value of 33.4%, where all the GW triggers from cWB are coincident with the list of LEN clusters with $> 5\sigma$ significance.

We then provide the result by using the Hud model in exchange of the SN1987A model. The FARs can be seen in Fig. 8 and the efficiency values in Tab. 5. This 2-parameter method gives us $\sim 7\%$ more recovered signals. We found that on average, the FARs the injections are $O(10^3)$ smaller with the 2-parameter than the 1-parameter for both emission models.

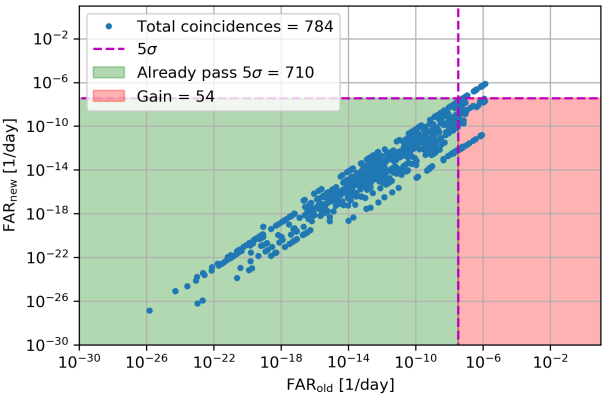

Fig. 8. The joint FAR of GW-LEN candidates obtained with the 2-parameter method ($\mathrm{FAR}_{\mathrm{new}}$ y-axis) vs the 1-parameter ($\mathrm{FAR}_{\mathrm{old}}$ x-axis) with the KamLAND-LVD (**Hud-model**) and HLV (Dim2-model) at 60 kpc.

Table 5. Efficiency comparison of the 1-parameter ($\eta_{1\mathrm{param}}$) and the 2-parameter ($\eta_{2\mathrm{param}}$) method for Fig. 8. The columns are analogous to Table 4.

Network & Type of Injections	Recovered $\mathrm{FAR}_{\mathrm{GW}} < 864$/d	$\eta_{1\mathrm{param}}$ [$> 5\sigma$]	$\eta_{2\mathrm{param}}$ [$> 5\sigma$]
HLV-KAM-LVD (Dim2-Hud)	784/2346= 33.4%	710/784= **90.6%**	764/784= **97.5%**

All in all, let us summarize the results. Fig. 2 for Dim2 model shows that the GW network HLV, by applying a threshold $\mathrm{FAR}_{\mathrm{GW}} \leq 864$/day, recovers about $\sim 33\%$ of the injected signals at 60 kpc. Notice that these GW triggers are far from statistically significant and clearly 0% passes a 5σ threshold. With this global network analysis and with our 2-parameter method, the multimessenger detection efficiency grows to $\sim 33\%$. If taking into account the weaker emission like Hud model, the detection efficiency arrives at the value of $33.4\% \cdot 97.5\% = 32.6\%$.

5. Conclusion

This paper is a timely description of the multimessenger strategy to combine GWs and LENs to search for CCSNe. More detail results will be discussed in a forthcoming paper[1] that has been accepted by JCAP.

Various models of GW and LEN emissions have been considered and used for a set of simultaneous injections into the background from the considered detectors. The data are then analysed with our proposed 2-parameter method comparing with the standard 1-parameter method. The performance is exercised at the level of efficiency estimation between these two methods for various analysis steps.

In general a multimessenger analysis can give a better efficiency to low-significant signals.

We highlight the improvement of the neutrino analysis with the ξ parameter in terms of FAR and FAP. This method could be of interest of the online alert system like SNEWS2.0.

All in all, the multimessenger campaign between GWs and LENs with the proposed method can increase the overall efficiency. Due to the higher sensitivity in LEN detectors, we can also do a targeted search in the (hopefully near) future to search for GWs from CCSNe.

The Lunar Gravitational–Wave Antenna is a proposed low–frequency gravitational–wave detector on the Moon surface. It will be composed of an array of high-end cryogenic superconducting inertial sensors (CSISs). A cryogenic environment will be used in combination with superconducting materials to open up pathways to low–loss actuators and sensor mechanics. CSIS revolutionizes the (cryogenic) inertial sensor field with a modelled displacement sensitivity at 0.5 Hz of 3 orders of magnitude better than the current state–of–the–art. It will allow the Lunar Gravitational–Wave Antenna to be sensitive below 1 Hz, down to 1 mHz and it will also be employed in the forthcoming Einstein Telescope—a third-generation gravitational–wave detector which will make use of cryogenic technologies and that will have an enhanced sensitivity below 10 Hz. Moreover, CSIS seismic data could also be employed to obtain new insights about the Moon interior and what we can call the Selene-physics.

Keywords: Inertial sensor, Superconducting, Cryogenic, Seismic sensor, Lunar science, Lunar gravitational-wave antenna, Einstein Telescope

1. Introduction

The development of the Cryogenic Superconducting Inertial Sensor (CSIS) originates in the Einstein Telescope (ET) framework. ET will need a highly precise sensor to monitoring motion effects caused by the low–vibration cooling applied to its penultimate suspension stage, which indeed will operate at cryogenic temperatures and in vacuum.[1] Because of its extreme sensitivity and capability of working at cryogenic temperatures, CSIS will also be deployed on the Moon, exploiting it as a detector to reveal gravitational waves (GWs). The Lunar Gravitational–Wave Antenna (LGWA)[2] aims to exploit Moon's response to passing GWs and its resulting

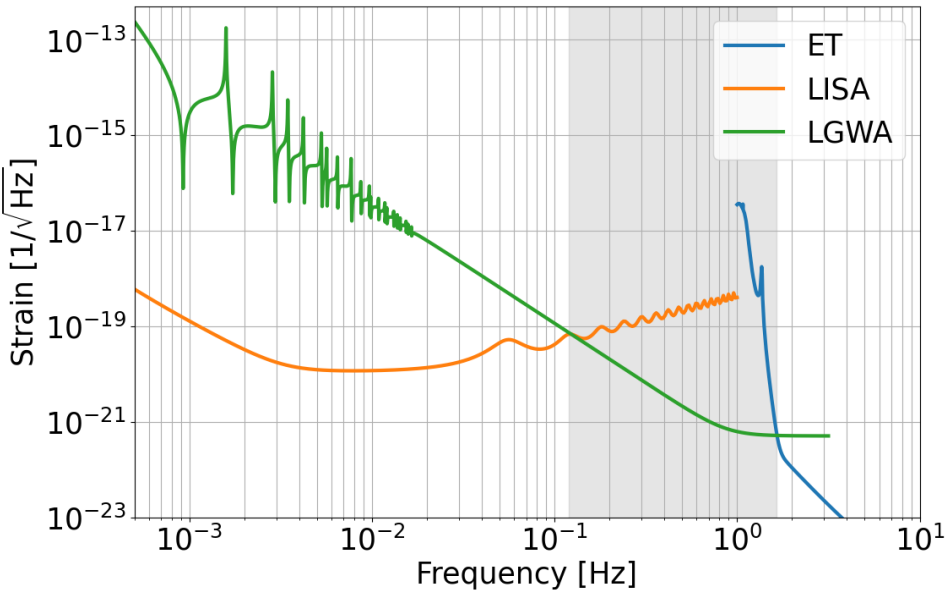

Fig. 1. Comparison in strain sensitivity between three future GW detectors. The notch–peak structures in the LGWA curve around 1–10 mHz result from the response of the Moon to passing GWs. Combining the performance of CSIS with the expected surface motion due to the lunar response yields the LGWA strain sensitivity. The grey rectangle highlights the gap that LGWA would bridge. See Ref.[2] for more info about the LGWA sensitivity curve.

surface motion. It will employ an array of 4 CSISs which can be regarded as the readout of a detector constituted by the Moon. The seismic data that LGWA would record will be used to study the Moon interior, its seismicity and its formation. This field of study is addressed as Selene-physics (the geophysics of the Moon).

LGWA will bridge the sensitivity gap between ET and the Laser Interferometer Space Antenna (LISA)[3] (see Fig. 1) between 0.12 and 1.5 Hz.

Improving detector sensitivity in the low–frequency band (below 10 Hz) entails a huge technical effort: Earth–bound GW detectors, like ET, are limited by the Newtonian noise,[4] while LGWA poses some difficulties deriving from deploying, assembling and powering the necessary instruments on the Moon.

The three detectors of which the sensitivity curves are shown in Fig. 1 are in development to extend our ability to detect GWs at lower frequencies. Signals of binary systems of (super–)massive black holes are found at these frequencies. Additionally, it will allow us to observe binary neutron stars already hours before the final merging.[5,6] Release of early warnings for the Electromagnetic (EM) follow–up will then be possible. The longer the observational time, the better the parameter estimation will be, also allowing to perform the sky–localization solely with the aid of LGWA (by exploiting the rotation of the Moon around the Earth). Polarization measurements and general relativity tests will also be possible.[2] Finally, it is

impossible to know, but exciting to imagine what kinds of unknown can be detected once we open up that low–frequency band.

2. A technical design for CSIS

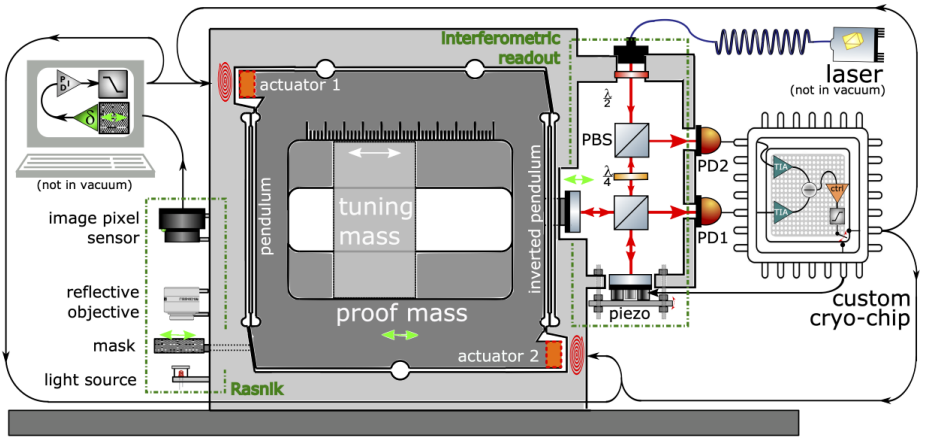

Fig. 2. Design of the CSIS sensor. We can identify four main parts: two readouts (highlighted by green dotted rectangles), spiral actuators (orange and red) and the proof mass (at the center). In Sec. 2 more details about the actuators and the proof mass are provided, while the two readouts are described in Secs. 3 and 4.

The design of CSIS is presented in Fig. 2. We can identify its four main parts: the Rasnik readout, the interferometric readouts, the two actuators on either side of the proof mass, and the niobium monolithic sensor mechanics. The latter will be the core of our sensor: a 1 kg mass suspended in a Watt's linkage configuration[7] (a combination of a pendulum and an inverted one) fabricated by Electrical Discharge Machining (EDM). The monolithic design allows to avoid having separate mechanical parts which would cause thermal dissipation.[8] Moreover, in Fig. 2 we see a tuning mass that will serve to adjust the resonance frequency of the sensor.

At cryogenic temperatures we can dramatically reduce the thermal noise, especially by employing materials that are superconductive ($T_c = 9.2$ K). At ~ 5 K the mechanical Q–factor of a niobium CSIS will be of the order of 10^4 (see Ref.[9]), which is a significant improvement with respect to the room temperature version. Concerning LGWA, permanent shadow zones (of the order of several km) on the Moon are a convenient way to provide low and stable temperatures (<40 K).[10] This will make less challenging reaching the temperatures where the niobium behaves as a superconductor.

The actuators of Fig. 2 will constitute of a thin layer of niobium deposited on a ceramic substrate and then attached to the sensor frame. By applying a current

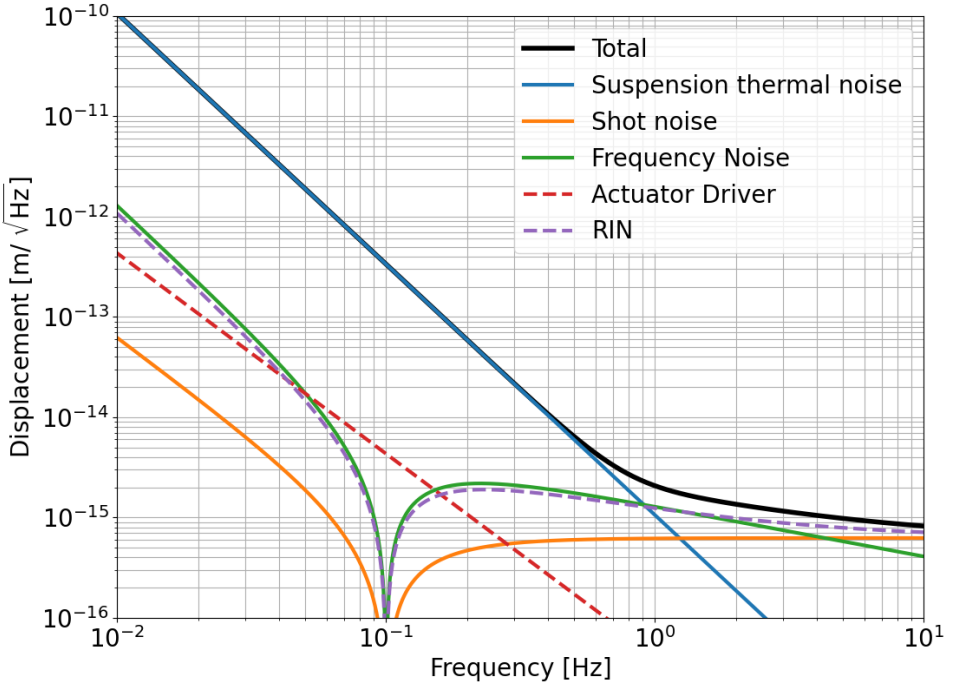

Fig. 3. Sensitivity and relative noises of niobium CSIS. The thermal noise was calculated considering a Q–factor of 10^4 and a temperature of 5 K. The other noises where calculated based on Ref.[9], where RIN is referring to the Relative Intensity Noise of the laser source of the interferometric readout and the actuator driver is calculated following Eq. 1.

to the spiral coil, a magnetic field will be created. Thanks to the Meissner effect, it will be expelled from the niobium of the proof mass, thus exerting a force on it.

To calculate CSIS sensitivity of Fig. 3, we need to take into account also the noise produced by the actuator driver:

$$n_{\mathrm{AD}} = \frac{\beta \mathrm{V_{DAC}}}{\mathrm{R_s m}\omega^2}, \tag{1}$$

where m is the mass, $\mathrm{R_s}$ is the sampling resistance (which determines the current into the actuator), $\mathrm{V_{DAC}}$ is the DAC voltage noise and β is the coil response value based on the latest simulations.

Another important advantage of employing a superconducting material is that it will avoid the thermal dissipation due to the eddy currents. This was a significant problem for the room temperature sensor version, where voice coils were employed to actuate the proof mass. In this way, the mechanical Q–factor was found to be highly limited by viscous damping associated with eddy currents induced on the moving metal surfaces by the voice coil stray field. The two readouts in Fig. 2 will be instead described in the next two sections.

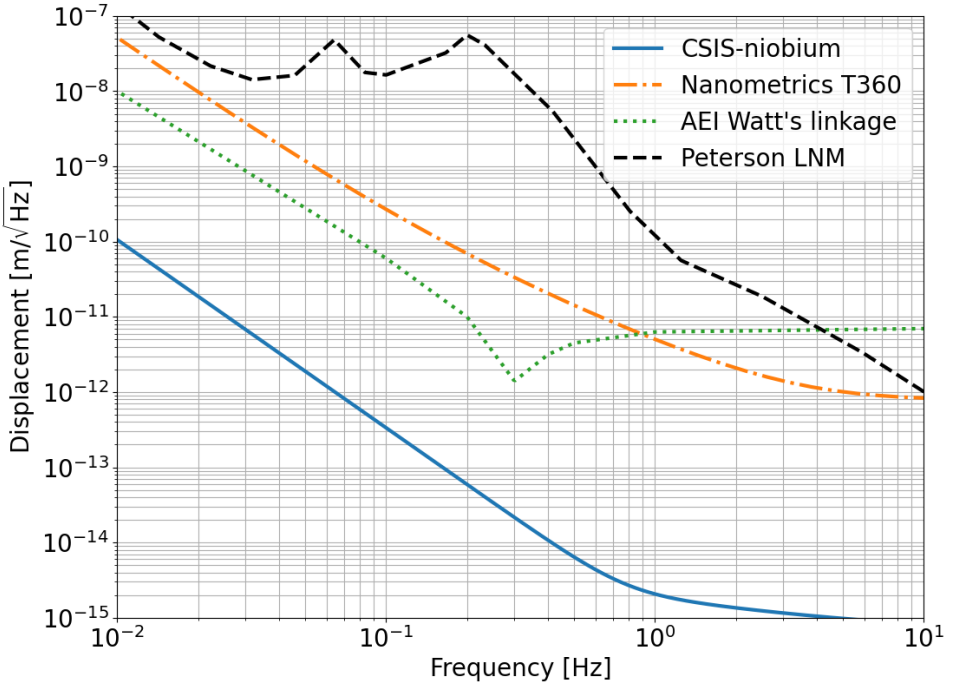

Fig. 4. Sensitivity of CSIS made of niobium compared to that of the most sensitive seismic sensors available. The Peterson's Low Noise Model (LNM) is depicted for comparison.

Thanks to its monolithic design, the employment of a material with a high Q-factor and thanks to two different readouts, CSIS will be able to reach sensitivities of 2 fm/$\sqrt{\text{Hz}}$ at 1 Hz (see Fig. 3). This is a factor 3000 better than the most sensitive seismic sensors (see Fig. 4, where the Peterson's Low Noise Model (LNM)[11] is depicted for comparison).

3. Interferometric readout

The interferometric readout that will be implemented in CSIS is based on that of Ref.[12] and it can be seen on the right side of Fig. 2 and in Fig. 6. It can be described as a simple Michelson interferometer with one more beamsplitter that allows to read the light coming back towards the laser. This second beamsplitter is needed to remove the common noise (such as intensity fluctuations in the laser power) by taking the differential signal between the two outputs. In this way, we can reach a shot noise limited sensitivity. The subtraction will be performed by a chip designed to work at cryogenic temperatures using CMOS technology.

The differential signal (see Fig. 5) will be fed through a control filter to the actuators which will dynamically lock the proof mass. This results in highly reduced relative motion between the proof mass and its frame and increased readout

dynamic range. Moreover, keeping the differential signal as close as possible to a fixed working point ensures optimal subtraction of the common noises. Indeed, in the room temperature version, it was found that the the desired shot-noise-limit performance was not yet achieved.[13] The reason was that there was still some residual motion of the proof mass, thus resulting in a sub-optimal subtraction of the two photodiodes signals. To solve this, we can use a second control loop to reduce as much as possible the residual motion of the proof mass: the Rasnik readout.

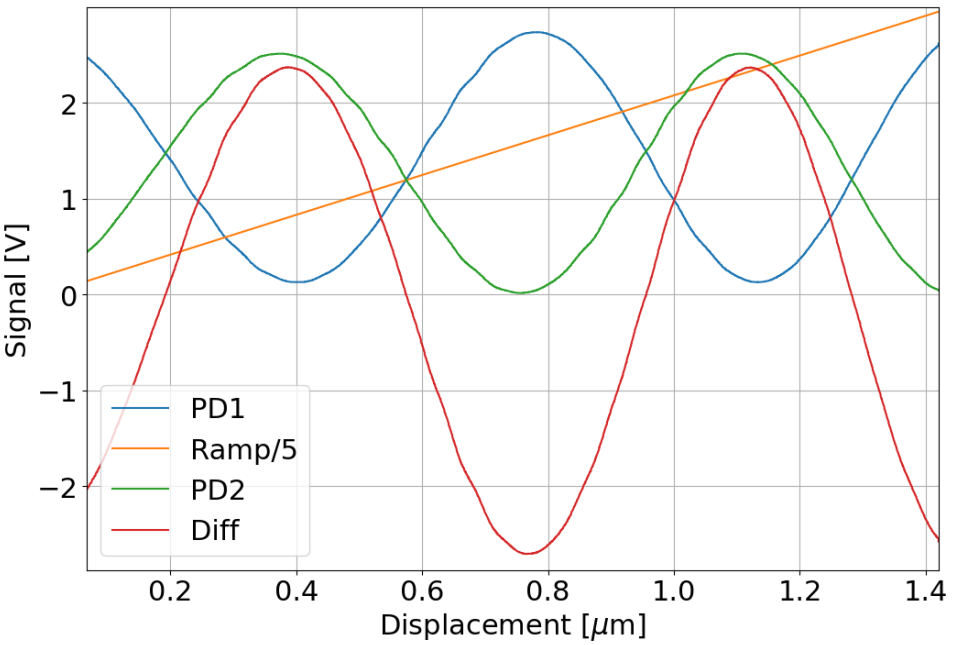

Fig. 5. Interference fringes obtained with a 1538 nm laser and moving one of the mirrors by injecting a ramp signal in its piezo actuator (PK44M3B8P2-Thorlabs). Using the known wavelength we find a piezo conversion factor of 96.1 nm V^{-1}. The minima and maxima are not exactly separated by the same distance probably due to non-linearities of the piezo actuator. The working points of the control loop are at 0 V of the differential signal.

Polarizing optics divert all the available power onto the photodiodes, avoiding dumping part of it. This is a important feature when working at cryogenic temperatures and it also means less shot noise for given injected power. Indeed, in Tab. 1 we can compare the powers received by the photodiodes and the overall shot noise when polarizing and non-polarizing optics are used. The total shot noise expected in the interferometer output depends on the amount of power falling on the photodiodes as $\mathrm{SN_i} \propto 1/\sqrt{P_\mathrm{i}}$. The total shot noise is then $\mathrm{SN_{tot}} = \sqrt{\mathrm{SN}^2_{\mathrm{PD}_1} + \mathrm{SN}^2_{\mathrm{PD}_2}}$.

We thus get a factor $\sqrt{3}$ of reduction in the shot noise when polarizing optics are employed with respect to the non-polarizing optics case.

Table 1. Comparison of interferometric readout outputs and shot noise without and with polarizing optics for a given input power P_0.

	power on PD1	power on PD2	SN_{tot}
previous configuration[12]	$P_0/4$	$P_0/8$	$\propto \sqrt{12/P_0}$
with polarizing optics	$P_0/2$	$P_0/2$	$\propto \sqrt{4/P_0}$

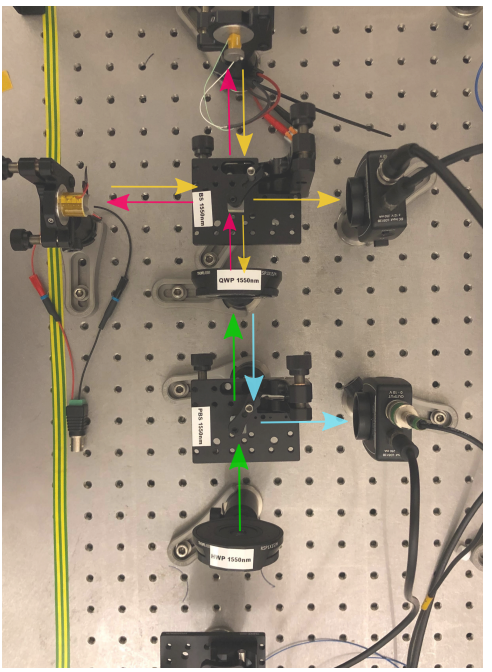

Fig. 6. Readout interferometer set up (laser on the bottom and photodiodes on the right). The arrows represent the light polarization: the green arrow right after the half wave plate (AHWP05M-1600-Thorlabs) is the linearly polarized light along the transmission axis of the polarizing beamsplitter (PBS104-Thorlabs), which, after passing through a quarter wave plate (AQWP05M-1600-Thorlabs), becomes circularly polarized (pink arrow). Reflection on the mirrors then reverses the handedness (yellow arrow). The second passage through the quarter wave plate with reversed handedness produces a linear polarization rotated by 90° degrees, which allows the light to be reflected by the polarizing beamsplitter instead of being transmitted.

4. Rasnik readout

The control loop driven by the Rasnik readout will have a larger dynamic range, capable of damping the proof mass resonance and thus reducing the proof mass residual motion. A Rasnik uses a back-lit chessboard mask which has its image projected via an objective on a pixel camera. The mask moves with the proof mass to which it is attached. The image that is recorded by the camera is then fed to a processing unit which performs a 2-dimensional Fourier transform. This transform will show a peak because of the many periodically spaced black-white transitions in the chessboard image. This peak shifts according to the motion of the mask and

a peak fitting algorithm returns then the Rasnik displacement measurement. The obtained sensitivity is 7 pm/$\sqrt{\text{Hz}}$ and a sub-pm/$\sqrt{\text{Hz}}$ sensitivity is expected given the implementation of certain improvements.[14] The beauty of this system is that its dynamic range is only dependent on the chessboard mask dimensions, which can be designed arbitrarily large.

5. Final remarks

The development of highly sensitive inertial sensors in the GW community opens the path to new GW detector concepts like LGWA, but also to the possibility of studying the Moon in more detail, giving rise to Selene-physics.

CSIS is the product of R&D in the ET community and it is the perfect candidate to be employed as readout in LGWA. It will reach a sensitivity of a few fm/$\sqrt{\text{Hz}}$ from 0.5 Hz onwards and, therefore, it will become the most sensitive inertial sensor capable of working at cryogenic temperatures in the low–frequency band.

Deci-hertz Interferometer Gravitational Wave Observatory (DECIGO) is the future mission that aims to detect gravitational waves between 0.1 Hz and 10 Hz. DECIGO has four clusters, and one cluster of DECIGO consists of three differential Fabry-Perot interferometers with three drag-free spacecraft. Among various science targets of DECIGO, the detection of primordial gravitational waves is crucial. We are now updating the DECIGO design to ensure the detection of the primordial gravitational waves. We aim to launch B-DECIGO first at the earliest in 2032 as a pathfinder mission of DECIGO. B-DECIGO will not only establish the necessary technologies for DECIGO, but also accomplish a variety of important sciences.

Keywords: DECIGO; B-DECIGO; interferometer; primordial gravitational wave

1. Introduction

Since the first detection of gravitational waves by LIGO and Virgo[1] in 2015, gravitational waves from various sources such as black hole binary, neutron star binary,[2] intermediate-mass black hole binary,[3] and black hole/neutron star binary coalescences[4] have been detected by LIGO and Virgo. Especially the neutron star binary coalescence was accompanied by short gamma-ray burst[5] and electromagnetic-wave observations of the afterglow.[6]

In the future, gravitational wave astronomy will be further developed by the third-generation ground-based detectors, such as Einstein Telescope (ET)[7] and Cosmic Explorer (CE),[8] as well as space detectors, such as LISA.[9] Ground-based detectors aim to detect gravitational waves above 10 Hz, while LISA aims below 0.1 Hz. Detection of gravitational waves from compact star binaries between the two frequency bands is useful because it can play a role of follow-up of the gravitational waves already detected by LISA, as well as a role of a predictor of the gravitational waves to be detected by the ground-based detectors. Furthermore, this mid-frequency band has the potential of establishing a deep and effective window for gravitational waves coming from various sources, not only because expected gravitational-wave signals are larger at lower frequencies, but also the confusion limiting noise caused by irresolvable gravitational wave signals coming from white dwarf binaries.

One of the future missions, aiming at detecting gravitational waves in this mid-frequency (between 0.1 Hz and 10 Hz), is Deci-hertz Interferometer Gravitational Wave Observatory (DECIGO).[10,11] In this paper, pre-conceptual design and aimed science of DECIGO are explained in sections 2 and 3. Then the necessary update of the DECIGO design is described in section 4. In section 5, B-DECIGO, which is a pathfinder mission of DECIGO with solid scientific targets, is explained. Finally, in section 6, conclusions are summarized.

2. Design of DECIGO

The concept of DECIGO was born in 2001. At that time, the main science target was the direct measurement of the acceleration of the Universe. Since then, we have elaborated the design of DECIGO by implementing Fabry-Perot arm cavities, and finally, we established a pre-conceptual design of DECIGO.

As shown in Fig. 1, one cluster of DECIGO consists of three differential Fabry-Perot interferometers with three drag-free spacecraft. Each spacecraft has two floating mirrors, which are shared by two interferometers. The relative position of the mirror with respect to the spacecraft is measured by local position sensors attached to the spacecraft, and the position signals are fed back to the thrusters attached to the spacecraft to control the position of the spacecraft. The distance between the two spacecraft is 1,000 km. Laser light illuminating the interferometers has a wavelength of 515 nm and a power of 10 W. The mirrors have a radius of 0.5 m and a mass of 100 kg. The Fabry-Perot cavities have a finesse of 10. There are four clusters altogether placed separately, with two clusters at the same place in the heliocentric Earth-trail orbit, as shown in Fig. 2. The separation of the spacecraft is useful to increase the angular resolution of the sources, while placing the two clusters at the same place is useful to take correlation measurements to detect stochastic gravitational-wave background, such as primordial gravitational waves.

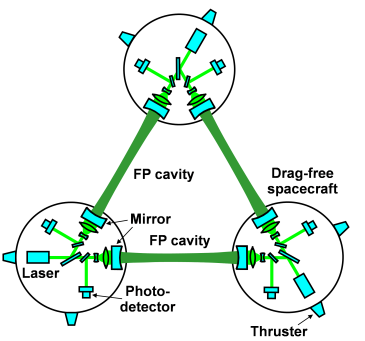

Fig. 1. Pre-conceptual design of DECIGO.

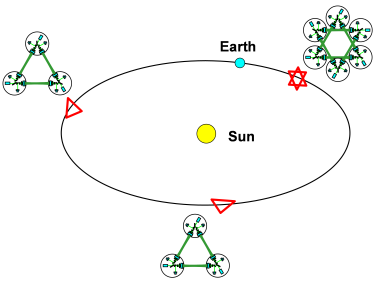

Fig. 2. Orbit of DECIGO.

3. Science of DECIGO

The target sensitivity of DECIGO and expected gravitational-wave signals from various sources are shown in Fig. 3. The target sensitivity of one cluster of DECIGO is $4 \times 10^{-24}\,\mathrm{Hz}^{-1/2}$ around 1 Hz. The sensitivity is limited by radiation pressure noise below 0.1 Hz and shot noise above 10 Hz. The shot-noise-limited sensitivity decreases above the cavity pole frequency, about 10 Hz, because the gravitational wave signals are canceled by the long storage time of the light in the arm cavities.

One cluster of DECIGO can detect gravitational waves coming from a large number of black hole binaries, for example, 1,000-solar-mass black holes at a redshift of $z = 10$ with a high signal-to-noise ratio. This could reveal the formation mechanism of intermediate-mass black holes. DECIGO can also detect gravitational waves from a large number of neutron star binaries, for example, at a redshift of $z = 1$ with a good signal-to-noise ratio. This can provide a prediction of the exact time and location of neutron star binary coalescences for ground-based gravitational-wave detectors as well as both terrestrial and space electromagnetic-wave observatories.[12]

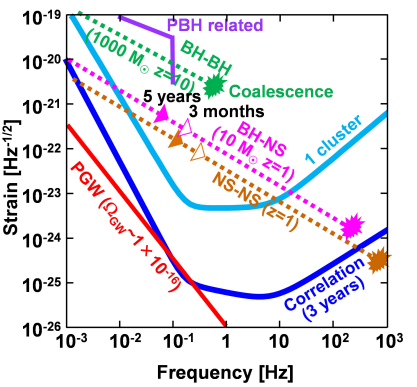

Fig. 3. Target sensitivity of DECIGO and expected gravitational wave signals.

This could also lead to the direct measurement of the acceleration of the expansion of the Universe, because it could cause a phase delay of gravitational wave signals.[10,13,14] This could provide reliable information about dark energy. DECIGO can also detect gravitational waves from, for example, about ten solar-mass black hole and neutron star binaries at a redshift of $z = 1$. This could provide a factor of 10^4 more precise test for the general theory of relativity.[15] In addition, DECIGO could detect gravitational waves coming from density fluctuations at the beginning of the Universe, which could have produced primordial black holes as candidates of dark matters.[16] DECIGO also has a variety of other science targets.[17–20]

The target sensitivity of DECIGO can be improved to $7 \times 10^{-26}\,\mathrm{Hz}^{-1/2}$ around 1 Hz by taking a correlation of two clusters st the same place for three years. This could enable detection of the primordial gravitational waves and revelation of the true inflation mechanism.[21] Moreover, DECIGO could observe a parity violation between the two circular polarizations,[22] separate the tensor, scalar, and vector modes of gravitational waves,[23] and reveal the thermal history after the inflation.[24,25] The design sensitivity of DECIGO was established more than ten years ago in such a way that DECIGO could detect the primordial gravitational waves corresponding to normalized energy of $\Omega_{\mathrm{GW}} = 2 \times 10^{-15}$, which was the upper limit of the primordial gravitational waves at that time. However, analysis based on the observations by the Planck satellite lowered the upper limit of Ω_{GW} to 1×10^{-16}. As a result, the DECIGO sensitivity became no longer good enough to detect the primordial gravitational waves.

4. Update of DECIGO design and target sensitivity

We are currently updating the design parameters of DECIGO, so that the new target sensitivity, determined by the updated design parameters, could ensure detection of the primordial gravitational waves with a good margin. We take the following three steps for the update. (1) For a given radius of the mirror, the cavity length, reflectivity of the mirrors, and laser power are optimized for the best signal-to-noise ratio, considering only the quantum noise as the noise source of DECIGO. (2) The same optimization is performed, considering other noise sources, such as the thermal noise of the mirrors. (3) The design and the corresponding sensitivity are updated, considering practical issues, such as the constraints of the mirror size.

We have completed the first step so far. For a given radius of the mirrors, we used a set of the three free design parameters (the cavity length, reflectivity of the mirrors, and laser power) to calculate the signal-to-noise ratio for the primordial gravitational waves. In the process of the calculation, optical loss due to the diffraction of the light, determined by the radius of the mirrors and the cavity length, was properly considered.[26] The signal-to-noise ratio was calculated between 0.1 Hz and 1 Hz, assuming that the confusion limiting noise caused by gravitational waves coming from extra-galactic white dwarf binaries does not exist above 0.1 Hz. The laser power of 100 W at the maximum was assumed to be available, although the default

design of the laser power for DECIGO is 10 W. The result of the optimization is shown in Fig. 4.[27] It indicates that by increasing the radius of the mirror from 0.5 m (default value) to 1 m, the cavity length can be extended from 1,000 km (default value) to about 5,000 km. This results in the improvement of the signal-to-noise ratio from 1.6 to about 100 with also the optimized reflectivity of the mirrors and laser power. It should be noted that in this optimization, the mass of the mirror is maintained to be constant, 100 kg (default value), even with the increased radius of the mirrors by shortening the thickness of the mirrors. We are now doing the same kind of optimization considering other noise sources, such as the thermal noise of the mirrors.

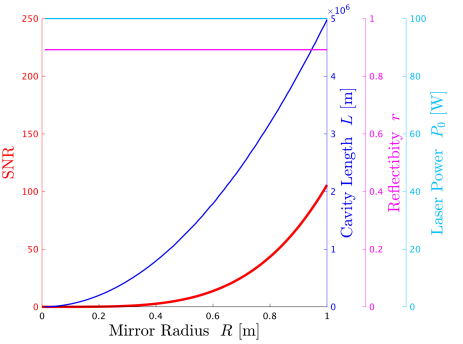

Fig. 4. Optimization of the cavity length, reflectivity of the mirrors, and laser power for a given radius of the mirrors in terms of the best signal-to-noise ratio.[27]

We are also investigating the possibility of implementing the quantum locking technique with an optical spring to DECIGO. We found that the quantum locking with an optical spring could improve the signal-to-noise ratio of the quantum noise to the primordial gravitational waves from 1.6 to 214 without changing the mirror size.[28,29]

5. B-DECIGO

We aim to launch B-DECIGO[30] at the earliest in 2032 before DECIGO. B-DECIGO can play a role in demonstrating the required technologies for DECIGO as well as a role of a real gravitational wave detector. B-DECIGO consists of three differential Fabry-Perot interferometers with three drag-free spacecraft. The distance between two spacecraft is 100 km, which is one-tenth of that of DECIGO. The laser wavelength is the same as that of DECIGO, and the laser power is 1 W (one-tenth of that of DECIGO). The mirror radius is 0.15 m (one-third of that of DECIGO), and the mass is 30 kg (one-third of that of DECIGO). The finesse of the arm cavities is 100 (ten times larger than that of DECIGO). B-DECIGO has one cluster, and the orbit is still under consideration.

The target sensitivity of B-DECIGO is shown in Fig. 5. The target sensitivity of B-DECIGO is lower than that of DECIGO approximately by a factor of ten. Since it has only one cluster, the correlation between the two clusters is not available. Although we cannot expect to detect the primordial gravitational waves, B-DECIGO can still bring us a variety of science.[31] It is expected to predict the timing of the neutron star binary coalescences together with the location of the source 100 times a year. It could reveal the origin of about 30 solar-mass black holes. It could estimate the parameter of compact star binaries much better than before. B-DECIGO could also demonstrate the method of removing the foreground gravitational wave signals coming from neutron star binaries, which is necessary for DECIGO. It could also demonstrate the technologies required to realize DECIGO, such as the Fabry-Perot cavities in space and drag-free system.

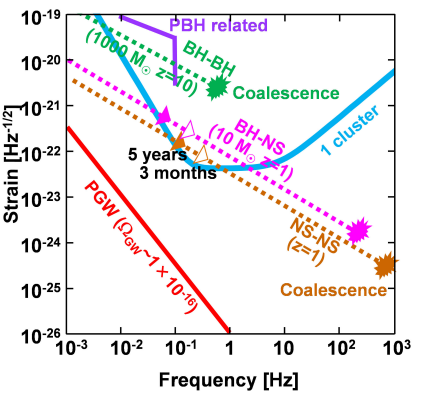

Fig. 5. Target sensitivity of B-DECIGO and expected gravitational wave signals.

6. Conclusions

DECIGO will accomplish a variety of outstanding sciences, including direct observation of the primordial gravitational waves. We are now investigating the improvement of target sensitivity of DECIGO to ensure the detection of the primordial gravitational waves. B-DECIGO will not only accomplish a variety of important sciences but also establish the necessary technologies for DECIGO.

This article summarizes the talks in the session GW2 of *the Sixteenth Marcel Grossmann Meeting on Recent Developments in Theoretical and Experimental General Relativity, Gravitation, and Relativistic Field Theories*, 5-10 July, 2021, on *Mid-frequency (0.1-10 Hz) gravitational waves: Sources and detection methods* with a review on strain power spectral density amplitude of various mid-frequency gravitational wave projects/concepts and with extended summaries on the progress of ZAIGA project and on the conceptual study of AMIGO.

Keywords: Mid-frequency gravitational waves; Earth-based gravitational wave detectors; Moon-based gravitational wave detectors; Space-borne gravitational wave detectors

1. Introduction

The mid-frequency GW (Gravitational Wave) band (0.1-10 Hz) between the LIGO-Virgo-KAGRA detection band and LISA-TAIJI/TIANQIN detection band is rich in GW sources. In addition to the intermediate BH (Black Hole) Binary coalescence, it can also come from the inspiral phase of stellar-mass coalescence and from compact binaries falling into intermediate BHs. Detecting mid-frequency GWs enables us to study the compact object population, to test general relativity and beyond-the Standard-Model theories, to explore the stochastic GW background and so on. In addition to DECIGO and BBO, the detection proposals under study include AEDGE, AIGSO, AION, AMIGO, DO, ELGAR, GLOC, INO, LGWA, MAGIS, MIGA, SOGRO, TIAGO, TOBA, ZAIGA, etc. Great advances have accumulated since MG15.

In the GW2 parallel session on 7 July 2021, there were ten talks.[1–10] First, an outlook of the mid-frequency GW detection and AMIGO were reviewed[1] followed by three talks on the mid-frequency astrophysical/cosmological sources and their propagation through the inhomogeneous universe for the GW observations from the Earth, the Moon and the Space.[2–4] The next two talks were on the Lunar Gravitational-Wave Antenna (LGWA) and its sensor development.[5,6] The last four talks were on Earth-based detectors TOBA,[7] ZAIGA[8] and AION,[9] and space-borne detectors AEDGE,[9] DECIGO[10] and B-DECIGO.[10]

Although there have been activities across all GW frequency spectrum,[11] current activities on GW detection are largely in the high-frequency band (10 Hz-10 kHz) of LIGO-Virgo-KAGRA and low-frequency band (0.1 mHz-100 mHz) of LISA-TAIJI/TIANQIN together with PTAs (300 pHz-100 nHz) and CMB polarization observations (1 aHz-10 fHz). Nevertheless, activities in the mid-frequency GW band have increased steadily since last decade. In the 2030s, ET and Cosmic Explorer will be deployed in the high-frequency band; LISA and TAIJI/TIANQIN will be deployed in the mHz low-frequency band. To complete the map, some mid-frequency GW detectors are desired to be deployed also. Table 1 lists the strain power spectral density (psd) amplitude at 0.1 Hz, 1 Hz and 10 Hz for various mid-frequency GW detectors together with the strain psd amplitude for ET at 1 Hz & 10 Hz and Cosmic Explorer at 10 Hz, and the strain psd amplitude for LISA at 0.1 Hz and for & TAIJI & TIANQIN at 0.1 Hz, 1 Hz and 10 Hz.

Harms *et al.*[31] have discussed ground-based GW detector concepts to extend the present ground-based interferometers' detection spectral range to middle-frequency band 0.1–10 Hz. They find that although there are no fundamental limits to the detector sensitivity in this band, the technical limits for the Newtonian-noise cancellation from infrasound and seismic surface fields are challenging to overcome.[31,32] Newtonian noise needs to be measured and subtracted. ET and Cosmic Explorer need to deal with this issue to certain extent and their sensitivity extends only down to 1 Hz and 5 Hz amplitudes respectively. ET is listed at 10 Hz and 1 Hz and Cosmic Explorer is listed at 10 Hz in Table 1 for comparison. On the lower frequency side, LISA, TAIJI and TIANQIN are listed for comparison. For space missions, local gravity noise (Newtonian noise needs to be compensated, and/or measured and subtracted. Due to the success of LISA Pathfinder mission,[33,34] this issue is largely solved.

The goal on the strain psd noise of ET at 1 Hz is $\sim 1 \times 10^{-21}\mathrm{Hz}^{-1/2}$, while that of LISA at 0.1 Hz is $4 \times 10^{-20}\mathrm{Hz}^{-1/2}$. Any new mid-frequency proposals aiming at a starting time after ET and LISA turn-on can keep these sensitivities in mind for their designs.

In Section 2, we discuss and review sources and scientific goals for mid-frequency GW detection. In Section 3, we discuss Earth-based detectors and summarize the TOBA, AION and ZAIGA talks. In Section 4, we discuss Moon-based detectors and summarize the LGWA and GLOC talks. In Section 5, we discuss space-borne GW detectors and summarize the AEDGE, AMIGO, DECIGO and B-DECIGO talks.

2. Sources and Scientific Goals

The general scientific goals of mid-frequency GW detectors are:

(i) to bridge the spectral gap between high-frequency and first-generation low-frequency GW sensitivities for detecting intermediate mass BH coalescence;

(ii) to detect inspiral phase and predict time of stellar-mass binary black hole coalescence together with neutron star coalescence or neutron star-black hole

Table 1. Strain power spectral density (psd) amplitude at 0.1 Hz, 1 Hz and 10 Hz for various mid-frequency GW detectors. In the first column, [E] means Earth-based, [M] means Moon-based, and [S] means space-borne. All units are in $\mathrm{Hz}^{-1/2}$.

coalescence for ground interferometers, e.g., the inspiral GWs from sources like GW150914;[35]

(iii) to detect compact binary inspirals for studying stellar evolution and galactic population;

(iv) to detect middle frequency GWs from compact binaries falling into intermediate mass BHs for multi-band observation with ground-based GW detectors;[36]

(v) to study the compact object population and to estimate/explore the astrophysical stochastic background from stellar object inspirals;

(vi) to determine Supermassive Black Hole properties using GW radiation from surrounding stellar-mass BH binaries;[3,37]

(vii) to test general relativity and beyond-the-standard-model theories.

In subsection 2.1, the goal (vi) will be discussed. General treatments on astrophysical GW sources and associated goals for detection in the middle-frequency GW bands can be found in Refs. [35, 36, 38, 39]. In subsection 2.2, Generation, propagation and detection of GWs in inhomogeneous universe will be discussed. In section 3-5, specific scientific goals for individual detector will be stated.

2.1. *Determination of Supermassive Black Hole properties using GW radiation from surrounding stellar-mass BH binaries*[3,37]

With space-borne gravitational-wave observatories, one may use stellar-mass BH binary as a signal carrier to probe modulations induced by a central supermassive BH (SMBH) to further place constraints on the SMBH's properties. As an example, Yu and Chen[3,36] showed that the de Sitter precession of the inner stellar-mass binary's orbital angular momentum around the angular momentum of the outer orbit would be detectable when the precession period is comparable to the duration of observation, typically a few years. The precession could be combined with the Doppler shift arising from the outer orbital motion to determine the mass of the SMBH and the outer orbital separation with percent-level accuracy. Joint detection with Earth-based detector would extend the detection threshold to a precession period to $\sim$100 yr.

2.2. *Generation, propagation and detection of GWs in inhomogeneous universe*

In the talk, Fier *et al.*[2,40] presented their recent studies on GWs produced by remote compact astrophysical sources. To describe such GWs properly, Fier *et al.* introduced three scales, the typical wavelength of GWs, the scale of the cosmological perturbations, and the size of the observable universe. For GWs to be detected by the current and foreseeable detectors, they can be well approximated as high-frequency GWs. The spatial, traceless, and Lorentz gauge conditions can be imposed simultaneously to simplify the field equations, even when the background is not vacuum, as long as the high-frequency GW approximation is valid. Fier *et al.* developed the geometrical optics approximation to such GWs, and calculated the gravitational integrated Sachs-Wolfe effects due to the presence of the cosmological scalar and tensor perturbations to read out explicitly the dependence of the amplitude, phase and luminosity distance of the GWs.

3. Earth-Based Detectors – TOBA, AION and ZAIGA

Earth is noisy for strain measurement. From 10 Hz to 10 kHz, vibration noise needs to be suppressed. This issue is basically solved by active and passive vibration isolation after decades of research and development. In the mid-frequency band of GW detection on Earth, the Newtonian noise (the gravity gradient noise) cannot be suppressed. It needs to be measured and subtracted. TOBA uses torsion bars, and AION and ZAIGA use atom interferometry to measure the Newtonian noise and subtract it.

3.1. *TOBA*

TOBA (TOrsion-Bar Antenna) is a mid.-frequency gravitational-wave antenna. It is formed by two bar-shape test masses, each suspended as a torsion pendulum. Tidal effect originated by incoming gravitational wave will be detected as differential angular motion of these two bars. The fundamental sensitivity is $10^{-19}\mathrm{Hz}^{-1/2}$ at 0.1 Hz frequency band, assuming 10-m scale cryogenic detector at 4 K with the rotations of the bars measured with Fabry–Perot cavities at the end of the bars.[7,18] Though this sensitivity is not comparable with space antennae, it is sufficient to observe some intermediate-mass black-hole inspirals in our universe. Also, operation on ground is advantageous in development time and cost. The Phase-III prototype is to complete the demonstration of noise reduction reaching a sensitivity of about $10^{-15}\mathrm{Hz}^{-1/2}$ at 0.1 Hz. Measuring the terrestrial gravity fluctuation with a sensitivity of about or below $10^{-15}\mathrm{Hz}^{-1/2}$ at 0.1 Hz is useful for two geophysical purpose – earthquake early warning and Newtonian noise reduction for GW detection.

3.2. *AION*

AION (Atom Interferometer Observatory and Network) is a proposed experimental programme using cold strontium atoms to search for ultra-light dark matter, to explore gravitational waves in the mid-frequency, and to probe other frontiers in fundamental physics. AION has 3 stages of development, AION-10 m, AION-100 m and AION-1 km in parallel to MAGIS-10 m, MAGIS-100 m and MAGIS-1 km. AION would share many technical features with the MAGIS experimental programme, and synergies would flow from operating AION in a network with MAGIS, as well as with other atom interferometer experiments such as MIGA, ZAIGA and ELGAR.[9,21]

3.3. *ZAIGA*

ZAIGA (the Zhaoshan long-baseline Atom Interferometer Gravitation Antenna) is a proposed underground long-baseline atom interferometer (AI) facility (see Fig. 1), aiming for experimental research on gravitation and related problems.[22] It is located in the mountain named Zhaoshan which is about 80 km southeast to Wuhan city.

ZAIGA will consist of gravitational wave detection (ZAIGA-GW), dark matter detection (ZAIGA-DM), high-precision test of the equivalence principle (ZAIGA-EP), clock-based gravitational red-shift measurement (ZAIGA-CE-R), rotation measurement and gravitomagnetic effect (ZAIGA-RM), and geological and geophysical measurement (ZAIGA-GG). The first stage of the project (2021-2025) will include building a vertical 300-meter long tunnel to interrogate three 10-meter atom interferometers and atomic clocks (aiming for ZAIGA-EP, ZAIGA-DM and ZAIGA-CE-R), and building a horizontal 1.5-km long tunnel (aiming for ZAIGA-RM and ZAIGA-GG). Depending on the performance in the first stage, the second stage of the project will construct an array of 1-km arm-length horizontal triangular tunnels and be dedicated to ZAIGA-GW.

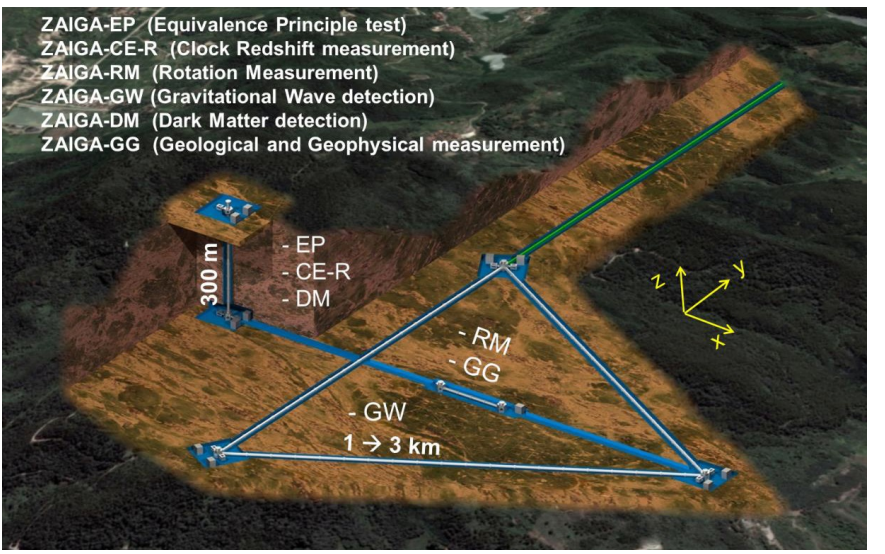

Fig. 1. Schematic diagram of ZAIGA design.

The site exploration started immediately after the ZAIGA plan was put forward. Relevant work for site exploration keeps on going now. The following progress on the technical and theoretical aspects of ZAIGA has also been made.

In the past three years, with our 10-m dual-species atom interferometer, we carried out a joint mass-energy test of the equivalence principle (EP), by using rubidium atoms with specified mass and internal energy.[41] By extending the four-wave double-diffraction Raman transition method (4WDR) to ^{85}Rb and ^{87}Rb atoms with different angular momenta, we can measure their differential gravitational acceleration. The Eötvös parameter, η, of the four paired combinations ($^{85}Rb|F = 2\rangle - ^{87}Rb|F = 1\rangle$, $^{85}Rb|F = 2\rangle - ^{87}Rb|F = 2\rangle$, $^{85}Rb|F = 3\rangle - ^{87}Rb|F = 1\rangle$ and $^{85}Rb|F = 3\rangle - ^{87}Rb|F = 2\rangle$) were measured to be $\eta_1 = (1.5 \pm 3.2) \times 10^{-10}$,

$\eta_2 = (-0.6 \pm 3.7) \times 10^{-10}$, $\eta_3 = (-2.5 \pm 4.1) \times 10^{-10}$ and $\eta_4 = (-2.7 \pm 3.6) \times 10^{-10}$, respectively. The violation parameters of mass and internal energy are constrained to $\eta_0 = (-0.8 \pm 1.4) \times 10^{-10}$ and $\eta_E = (0.0 \pm 0.4) \times 10^{-10}$. This work opens a door for joint tests of two attributes beyond the traditional pure mass or energy tests of EP with quantum systems. It also provides us a firm technical foundation for our proposed ZAIGA-EP experiment. For the rotation measurement, Yao *et al.* in our group has improved the precision of the measurement by one-order of magnitude recently and keep on advancing the precision and accuracy.[42]

Recently, a theoretical study on the possibility of detecting the ultralight scalar dark matter (DM) with ZAIGA was completed.[43] Starting with a popular scalar DM model, where the DM field is assumed to linearly couple to the standard model fields through five coupling parameters, the DM candidate can be detected by determining whether the five coupling parameters are zero or not. The solution to the DM field contains a background oscillation term and a local exponential fluctuation term. The DM signals in ZAIGA has been calculated. For a pair of AIs vertically separated by 300 meters, the DM-induced differential phase consists of three contributions, coming from the DM-induced changes in atomic internal energy levels, atomic masses and the gravitational acceleration. For a pair of AIs horizontally separated by several kilometers, the signal comes only from the DM-induced changes in atomic internal energy levels. The constraints on five DM coupling parameters for ZAIGA-DM have been estimated. It turns out that the proposed constraints would complement the MICROSCOPE space experiment[44] and would be several orders of magnitude better in higher-mass parametric regions. It also clearly shows the advantages and disadvantages of the two configurations of ZAIGA-DM. For the vertical configuration, the advantage is that all the five DM coupling parameters can be constrained, and the disadvantage is that the arm-length is not easy to extend. For the horizontal configuration, the advantage is that the arm-length is relatively easy to extend, and the disadvantage is that only two DM parameters can be constrained. For other type of DM candidates, the relevant studies are in progress.

4. Moon-Based Detectors – LGWA and GLOC

Moon is much quieter seismologically and does not have an atmosphere. This makes Moon itself a possible good detector by monitoring its surface motion excited by GWs. This also makes an interferometer GW detector based on the Moon possible.

4.1. *Lunar Gravitational-Wave Antenna*[5,23]

One of the first concepts proposed for the detection of gravitational waves by Joseph Weber is to monitor the quadrupolar vibrations of elastic bodies excited by GWs. At laboratory scale, these experiments became known as resonant-bar detectors, which form an important part of the history of GW detection. Due to the dimensions of

these bars, the targeted signal frequencies were in the kHz range. It was also Weber who suggested to monitor vibrations of Earth and Moon to search for gravitational waves in the mHz band. His Lunar Surface Gravimeter was deployed on the Moon in 1972 by the Apollo 17 crew. A design error made it impossible to carry out the intended search for GWs, but the idea remains intriguing. Harms *et al.*[5,23] have proposed a new concept, the Lunar Gravitational-Wave Antenna (LGWA), based on Weber's idea. LGWA would have a rich GW and multi-messenger science case with galactic binaries and more massive black-hole binaries. It would also serve as a high-precision geophysical station shedding light on the interior structure of the Moon, the mechanisms of moonquakes, and the Moon's formation history. The key component is a next-generation, high-sensitivity seismometer to be deployed on the Moon. For its most sensitive realization, LGWA would have to be deployed in a permanent shadow near the south or north pole of the Moon to benefit from the natural cryogenic environment. This would improve the sensitivity of the seismometer and also provide a lower-noise environment due to the absence of thermally induced seismic events that were observed by the Apollo seismometers. Powering of the seismic stations and data transfer pose additional challenges for such a deployment.

4.1.1. *Inertial sensors for the LGWA*[6]

The core of LGWA will be composed of an array of high-end seismic sensors: CSIS (Cryogenic Superconducting Inertial Sensor) on the Moon's surface. A cryogenic environment will be used in combination with superconducting materials to open up pathways to low-loss actuators and sensor mechanics.

CSIS revolutionizes the (cryogenic) inertial sensor field by obtaining a displacement sensitivity at 0.5 Hz of 3 orders of magnitude better than current state-of-art. It will allow LGWA to be sensitive below 1 Hz, down to 1 mHz. It will also be employed in the forthcoming Einstein Telescope (ET) - a third-generation gravitational-wave detector that will make use of cryogenic technologies and will have an enhanced sensitivity below 10 Hz. Moreover, CSIS seismic data could also be employed to get new insights about the Moon's interior... and the selenphysics (the Moon's geophysics). A technical design for CSIS with both interferometric readout and Rasnik readout is presented at the meeting.

4.2. *GLOC (Gravitational-Wave Lunar Observatory for Cosmology)*[4,24]

Taking advantage of the vacuum environment and the low seismic activities of the Moon, GLOC proposes to build a full laser-interferometric triangle-shape GW detector with 40 km arm length to explore fundamental cosmology and multi-band, multi-messenger astrophysics from the Moon. The speaker focused on goals that are unique to GLOC, and compare the detection landscape of the elusive intermediate-mass black holes between GLOC and other prominent space-based missions, 3G detectors and deci-Hertz concepts.

5. Space-Borne GW Detectors

The space environments are much quieter in terms of the gravity gradient noise consideration as compared to the Earth and Moon environments. It is so quiet that the major gravity gradient noise comes from local environments inside the spacecraft. In space, the GW strains propagating to the detector are measured above the geodetic motion or the desired controlled motion/position of the spacecraft. For spacecraft to follow geodesics, one needs to perform drag-free control. For spacecraft to follow desired motion/position over the geodetic motion, one needs to actuate acceleration on the geodetic motion in addition to basic drag-free control. LISA Pathfinder launched on December 3, 2015 has completely met the LISA drag-free noise requirement and has successfully demonstrated the first generation drag-free technology requirement for space detection of GWs.[33,34]

Many space GW detection proposals need to use constant/equal arm configurations. They are AEDGE,[9,25] AIGSO,[26,45] DECIGO/B-DECIGO,[10] etc. AIGSO has 10 km arm length, the shortest arm length among these mission proposals. The calculated actuation acceleration needed to maintain such orbits for AIGSO is around 10 pm s^{-2}.[45,46]

In the mission of LISA Pathfinder, different levels of force and torque authority were implemented, from the nominal configuration with x-force authority (on the sensitive line-of-sight axis) of 1100 pm s^{-2} to the URLA configuration levels, with x-force authority of 26 pm s^{-2}.[47] The published LPF differential acceleration noise floor is established by measurements in this configuration. Specifically, LISA Pathfinder demonstrated that when a constant out of the loop force with amplitude of 11.2 pN was applied to the sensitive axis of TM1 (Test Mass 1) for reducing the gravitational imbalance between the TMs, this force does not introduce significant noise or calibration errors.[47] Basically, the accelerometer part of the constant-arm technology is already demonstrated by LISA Pathfinder for AIGSO.

B-DECIGO has a nominal arm length of 100 km, DECIGO 1,000 km, and AMIGO 10,000 km. The actuation accelerations needed are respectively 10, 100, and 1000 times more than AIGSO. While the actuation accelerations needed for constant arm implementation of b-DECIGO and DECIGO is still basically in the LISA Pathfinder nominal configuration range, the actuation accelerations for constant arm AMIGO is one order larger. On what noise level could the actuation accelerations be done is an issue that needs to be studied and demonstrated carefully for AMIGO. A suggestion is to use an additional test mass (i.e. a pair) to alternate with the original one.[46,48]

GW space missions do not usually require large communication capacity. The deployment to 2-4 degrees behind or ahead of the Earth orbit is no more complicated as to L1 or L2 Sun-Earth Lagrange points. We hereby provide *an example for taking less than a week to reach the (pre)-science orbits.* A last-stage launch from 300 km LEO (Low Earth Orbit) to an eccentric Hohmann orbit with apogee 262931 km (The period of this Hohmann transfer orbit is about 6 days.) (Fig. 2). It takes 3 days

(half an elliptic orbit) for this transfer from perigee to apogee (Fig. 2. (b)). This apogee can be designed to be the closest encounter point with respect to Earth of the center of mass of the 3 S/C traced back in time geodetically of the 2-degree-behind-the-Earth formation. From here, a Δv_1's of about 1.6 km/s are needed to allow the 3 S/C to enter their respective (pre-) science orbits (Fig. 2. (c)) when the calibration, commissioning and various science operations can be started. For example, it is the AMIGO-S-2-4deg orbit for AMIGO and the time epoch to reach the 2-degree-behind-the-Earth point is 2030-Jan-1st 12:00:00.[48] (AMIGO-Earth-like solar orbits with the AMIGO formation varying between 2 and 4 degrees behind the Earth orbit starting at epoch JD2462503.0 (2030-Jan-1st 12:00:00) in J2000 mean-equatorial solar-system-barycentric coordinate system.) There are similar orbit configurations for other time epochs and for ahead of the Earth situations. For ahead of the Earth situations, the apogees of the Hohmann orbits need to be on the other side of the Earth.

In the following, we summarize AEDGE,[9] AMIGO,[1] and DECIGO and B-DECIGO[10] in our session.

5.1. *AEDGE*[9,25]

Atomic Experiment for Dark Matter and Gravity Exploration (AEDGE) is a concept for a space experiment using cold atoms to search for ultra-light dark matter, and to detect gravitational waves in the mid-frequency band. It will also complement other planned searches for dark matter, and exploit synergies with other gravitational wave detectors. Examples are given in the talk of how its gravitational-wave measurements could explore the assembly of super-massive black holes, first-order phase transitions in the early universe and cosmic strings.[9,25] AEDGE will be based upon technologies now being developed for terrestrial experiments using cold atoms, and will benefit from the space experience obtained with, e.g., LISA and cold atom experiments in microgravity.

5.2. *AMIGO*

In 2017, a middle-frequency GW mission AMIGO (Astrodynamical Middle-frequency Interferometric GW Observatory) with arm length 10000 km was proposed to have significant sensitivity in this frequency band 0.1 Hz-10 Hz to bridge the gap between the ground detection sensitivity and the LISA sensitivity and yet to be a first-generation candidate for space GW missions.[51] The basic mission concept is in Ref. [51]. Stellar-size black hole inspirals[35] such as the ones like GW150914 will be sure sources of AMIGO. The AMIGO observation of the inspiral phase of these sources will enable us to predict the coalescence time precisely for the ground multi-messenger observations.

In [48], first studies on possible schemes of implementation of AMIGO were presented. Both the solar orbit and earth orbit options together with deployment

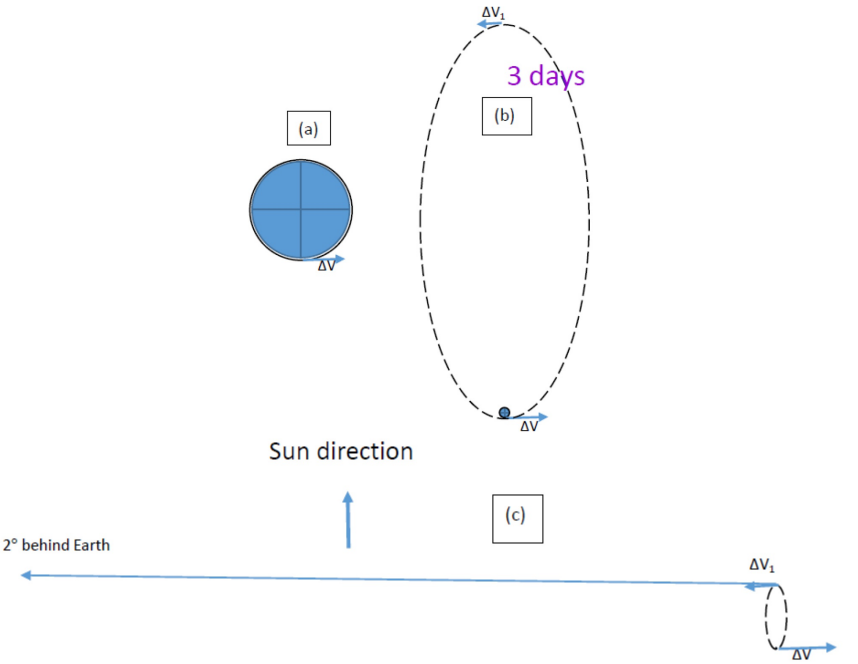

Fig. 2. An option for taking less than a week from launch to reaching the (pre-)science orbit for AMIGO-S-2-4 deg. (a) Launch to 300 km LEO (Low Earth Orbit) parking orbit. (b) A last-stage launch from 300 km LEO to an eccentric Hohmann orbit with apogee 262931 km (The period of this Hohmann transfer orbit is about 6 days.); It takes 3 days (half an elliptic orbit) for this transfer from perigee to apogee. (c) This apogee is designed to be the closest encounter point with respect to Earth of the center of mass of the 3 S/C traced back in time geodetically of the 2-degree-behind-the-Earth AMIGO formation]. From here, Δv_1's of about 1.6 km/s are needed to allow the 3 S/C to enter their respective (pre-)science orbits reaching 2-degree-behind-the-Earth at 2030-Jan-1st 12:00:00.[28,49,50]

strategy were discussed. The first-generation TDIs (Time Delay Interferometry's) for all orbit options studied were calculated and found that all the heliocentric orbit options satisfy the frequency-noise suppression requirement, but the geocentric orbit options do not satisfy the requirement. From this study, the heliocentric option is preferred. The issue on feasibility of constant equal-arm implementation was studied. For the solar-orbit options, the acceleration to maintain a constant equal-arm formation can be designed to be less than 15 nm/s^2 with the thruster requirement in the 15 μN range.[46,48] AMIGO would be a good place to test and implement the constant equal-arm option. Fuel requirement, thruster noise requirement and test mass acceleration actuation requirement were considered.

In [28], the core noise requirements on position noises and acceleration noises were updated. From these design white position noises and acceleration noises, the GW sensitivities (Fig. 3) were obtained for the first-generation Michelson X TDI configuration of b-AMIGO (baseline AMIGO), AMIGO, and e-AMIGO (enhanced

AMIGO). In Fig. 3, the sensitivities for the corresponding AMIGO-5's (50,000 km nominal arm length) are also shown. Steps to implement the AMIGO mission concept were indicated in view of the current technology development.

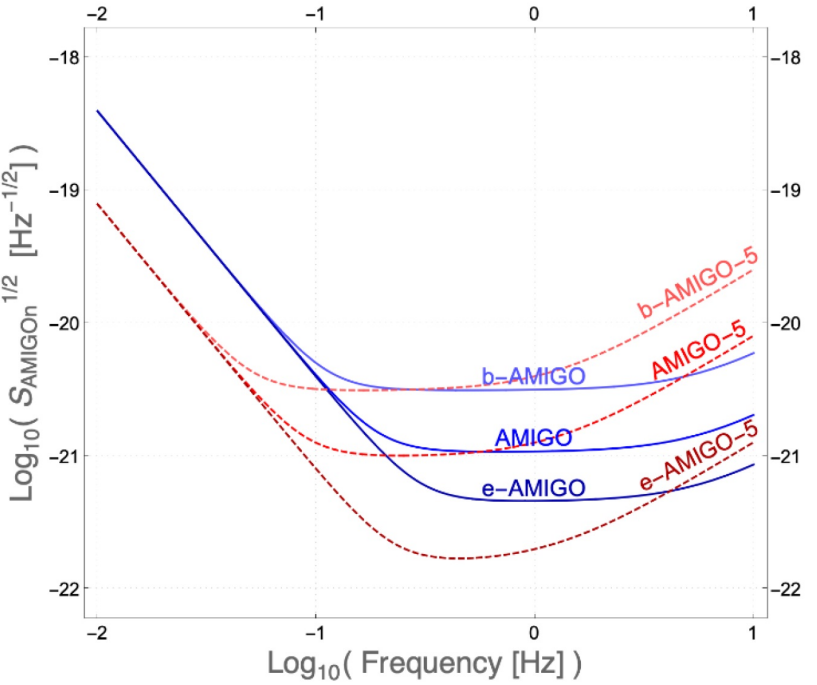

Fig. 3. Strain power spectral density (psd) amplitude vs. frequency for various AMIGO-5 proposals as compared to AMIGO proposals. The solid lines are for AMIGO's (10,000 km nominal arm length); the dashed lines are for AMIGO-5's (50,000 km nominal arm length).[28]

5.3. *DECIGO and B-DECIGO*[10]

DECIGO was conceived in 2001 with the main scientific target to directly measure the acceleration of the Universe. The design has been elaborated with laser Fabry-Perot arm cavities. DECIGO consists of four clusters with each cluster having three differential Fabry-Perot interferometers with three drag-free spacecraft forming an equilateral triangle of nominal arm cavity length 1000 km. Lasers illuminating the cavity have power 10 W and wavelength 515 nm. The current design has main mirrors with diameter 1 m and mass 100 kg forming cavities of finesse 10. The four clusters also form a nearly equilateral triangle in the heliocentric orbits with two clusters in Earth-trailing orbits. The other two clusters are separated from each other and from the near-Earth clusters by 120 degrees in the heliocentric orbits. The DECIGO team recognized that "... analysis based on the observations

by the Planck satellite lowered the upper limit of GW to 1×10^{-16} As a result, the DECIGO sensitivity became no longer good enough to detect the primordial gravitational waves". Nevertheless, with target sensitivity the best among all the present mid-frequency concepts (Table 1), it may still bring us some clues on the very early universe, e.g. revealing the thermal history after the inflation[52,53] etc.

The design of B-DECIGO is down-scaled from DECIGO, consisting of one cluster with three spacecraft separated from each other by 100 km. The arm cavity mirrors have diameter of 0.3 m with mass of 30 kg, and cavity finesse of 100. The laser wavelength is 515 nm and laser power 1 W. With target strain psd amplitude about one order higher than DECIGO, it serves as a pathfinder for DECIGO, and with the noise sensitivity well enough, it is also a good probe to the many mid-frequency GW sources discussed in section 2. DECIGO team aim to launch B-DECIGO at the earliest in 2032.

6. Discussion and Outlook

Middle frequency band (0.1-10 Hz) is important for GW detection to bridge the gap between high-frequency GW detection and low-frequency GW detection for various scientific goals. We have seen various proposals. It is hopeful to have some mid-frequency GW detectors in the 2030s to do multiband astronomy and multi-messenger astronomy.

Matched-filter based PyCBC searches have successfully detected $\sim \mathcal{O}(50)$ compact binary merger signals in the LIGO-Virgo data. While most PyCBC searches have been designed to detect stellar-mass binaries, we present here a new search that is optimised to detect short-duration gravitational wave (GW) signals emitted by intermediate-mass black hole mergers. When applied to the first half of the third observation run data, the optimised search re-identified the intermediate mass black hole (IMBH) binary event, GW190521, with a false alarm rate of 1 in 727 yrs, significantly lower than the previous PyCBC search result of 1 in 0.94 yr. Analysis of simulated signals from IMBH binaries with generically spinning components shows an increase in sensitivity by a factor of 1.2 to 3 over previous PyCBC searches.

Keywords: Gravitational Waves, Matched-Filtering, Intermediate-Mass Black Holes

1. Introduction

Coalescing compact binaries are amongst the primary sources of gravitational wave (GW) with frequencies accessible to current second-generation ground-based GW interferometers. Detection of $\sim \mathcal{O}(50)$ stellar-mass binary mergers (the majority being the binary black holes) has already ushered us into the age of observational strong-field gravity. They have so far given us unique insights into the black hole population that we hardly knew existed, with one of them being the first confirmed detection of a massive black hole system GW190521 with a remnant IMBH.[1,2]

GW190521 was observed in the first half of the third observing run of the Advanced LIGO and Advanced Virgo detectors. The compact binary merger event lasted for ~ 0.1 s in the detector band and had barely any observable pre-merger phase of the signal, clearly reflecting the binary's high total mass. The detailed Bayesian parameter estimation showed the merger event to be consistent with the merger of two black holes in a mildly precessing orbit, with component masses of $85^{+21}_{-14}\,M_\odot$ and $66^{+17}_{-18}\,M_\odot$ and a remnant black hole of $142^{+28}_{-16}\,M_\odot$ falling in the mass

range of intermediate-mass black holes.[1] The merger event producing this remnant was detected by a search sensitive to generic transient at high confidence with a false alarm rate of $< 1/4900$ years.[3]

Traditionally, the unmodeled GW transient search for short-duration GW signals is performed using the coherent waveburst (cWB) search[4] which is built on the rationale that a GW signal from a compact binary coalescence (CBC), chirp or not, is expected to be a transient waveform and it will produce some localised excess of energy if projected in the time-frequency plane. Therefore, identifying such an excess coherently across two or more detectors should give a strong indication of a GW event. Together with this, model-based matched-filter searches, such as PyCBC[5–9] and GstLAL,[10] targeting generic binaries have also been used for the IMBH binary searches in the LIGO-Virgo data (ADD O1-O2 and O3 paper link).

While unmodeled cWB searches are tuned to look for short-duration signals,[11] the standard matched-filter-based searches were not. The lack of *optimisation* towards IMBH binary signals made them suffer from the "look-elsewhere" effect. Further, improvements in the sensitivity of the detectors at low frequencies[12–14] before the beginning of the third observing run of Advanced LIGO and Advanced Virgo (O3) motivated us to adapt our matched-filter algorithms to the target search space. Here, we will summarise the salient features of one of the optimised templated searches, namely PyCBC-IMBH that was developed and deployed for the IMBH binary search. This optimised search was used together with other search pipelines to look for IMBH binaries in the O3 run, and the reader can find the results of it in.[15] For complete information on the algorithm itself, we direct the reader to the optimised PyCBC IMBH search paper.[16]

2. The Optimised PyCBC-IMBH Search

Below we summarise the salient features of the optimised PyCBC-IMBH search.[16]

Data cleaning: The gravitational wave strain data is often plagued with loud background noise, which can significantly hamper the search sensitivity.[17] Thus, we begin our analysis by windowing out very high amplitude excursions ($> 50\sigma$ deviation from Gaussian noise) in the whitened data.[6] Since empirically, these loud noise transients tend to be correlated with neighbouring quieter noise transients, we also *discard* any LIGO triggers which are either 1s before or 2.5s after the centre of the gating window.[16]

Template bank: After this data cleaning process, we use matched-filtering to detect the target signals hidden in the detector noise.[5,18,19] We assume that our target signals are well-modelled and deterministic, and to a good approximation, we can consider them to be buried in wide-sense stationary Gaussian noise. However, the binary's parameters are not known a priori, forcing us to use a discrete bank of filter waveforms, aka templates. Our bank of templates is designed to intercept the dominant quadrupolar harmonics of a non-precessing binary.[20] Specifically,

we use the reduced-order representation of the spinning effective one-body model, SEOBNRv4,[21,22] for our templates, and we *constrain* ourselves to binaries with redshifted (detector frame) total mass between $100 - 600 M_{\odot}$.[16] Additionally, our templates have a minimum component mass of $40 M_{\odot}$ and a mass ratio between 1/1 and 1/10. We do not use relatively lower mass ratios in the templates as binaries with low mass ratios emit gravitational wave signals with significantly higher subdominant harmonics that are not modelled by our waveform approximant. We also don't include any templates with a duration less than 0.07 s., measured from a fixed starting frequency of 15 Hz, to reduce the false alarms arising from short-duration noisy transients. Since information on the spins of IMBH binaries is lacking, we allow our templates to have dimensionless spin components along the orbital angular momentum to be between ± 0.998. The reader can find additional details about the template bank in.[16]

Although our search targets non-precessing binaries, we expect our search to retain its sensitivity towards moderately precessing binaries, mainly because our target systems are relatively short-lived within the detector bandwidth.[23,24] Furthermore, we also expect our search to be equally sensitive to binaries with low eccentricity as the emission of gravitational waves will circularise the binary system before the merger, and because of the shortness of our templates and the detector bandwidth, we will only be able to intercept the last few cycles of IMBH binary's inspiral.[25]

Time-phase consistency between detectors: Single-detector triggers are identified based on peaks in the matched filter signal-to-noise ratio (SNR) time series. Unfortunately, our detector data is polluted with several non-stationary instrumental artefacts that are not loud enough to be gated out during data pre-processing. Technically, this makes our search a detection problem in non-Gaussian noise. Having a network of simultaneously operating similar sensitivity detectors help a lot as we can demand that the time difference between triggers at different detectors is consistent with an astrophysical signal, i.e. within the light-travel time up to expected uncertainty. Besides, if the trigger is due to a GW signal, then it must share consistent phase and amplitude characteristics. Hence the *coincidence test* significantly reduces the number of noisy artefacts that is picked up by the search.

Signal consistency tests: But there can be chance coincidences between noise triggers. So, before the coincidence test is performed, there is a need to differentiate a signal from a glitch at the single detector level. We do this in multiple stages. We begin by only considering the loudest trigger within a pre-determined window of time to reduce false alarms, and we subject these triggers to two different signal-consistency tests: the χ^2_r-test[26] and the $\chi^2_{r,sg}$-test.[27] The former checks if the morphology of the triggers matches with that of the best-matched template, while the latter checks for any excess power beyond the maximum frequency of the template. The output of these two tests is used to amend the trigger SNR to reduce the apparent loudness of a noise trigger as the target signal will return values closer

to unity. We also account for any short-term non-stationarity of the detector noise that can lead to wrongful estimation of the trigger SNR.[28–30]

Given our target space, our search is susceptible to short but loud noise triggers motivating us to use stricter discriminators. We chose to discard any trigger with $\chi^2_r > 10$ or with short-term power spectral density (PSD) measure of over ten times the expectation from stationary noise.[16]

Event significance and ranking: We subject the surviving single-detector triggers to the coincidence test and assign each *multi-detector candidate* a rank based on their response to the coincidence test.[8,9] Our candidate events can be coincidentally observed either in one of the possible two detector combinations or in all three detectors. This is because we analyse all possible two and three detector combinations. Finally, a statistical significance is assigned to each of these candidates by comparing its rank against simulated background noise that is generated by finding fictitious coincidences between detector data.[6] We achieve this by shifting the pivot detector(s) data with respect to a fixed reference detector by a time that is considerably larger than the light-travel time between the detectors. By repeating this procedure, we produce more than 10^4 years worth of noise background.

In the next section, we provide details of how the PyCBC algorithm benefits from the optimisation made.

3. Summary of Sensitivity Comparison

To quantify the benefit of our restricted analysis, we compared the sensitivity of our optimised search against existing PyCBC-based searches with overlapping parameter space.[16] We compared the PyCBC-IMBH search against the PyCBC-broad and the PyCBC-BBH search. The former looks for binaries consisting of either neutron stars or black holes or both, while the latter is a "focused" search for binary black hole (BBH) covering a restricted range of masses. We resort to an injection campaign for the comparison. This involved adding simulated signals to real GW data from the first half of the third observing run (O3a) run as part of the analysis without any physical actuation and then estimate the sensitivity of each of the searches in terms of sensitive volume time $\langle VT \rangle$.[31,32] Our simulated signals mimicked those from generically spinning BBH with detector frame total mass between $100 - 600 M_\odot$ and having a mass ratio between $1/1 - 1/10$. The signals themselves were either the dominant quadrupolar mode or the full symphony emitted by such binaries. We found that the PyCBC-IMBH search is $\sim 1.2 - 3$ times more sensitive than the PyCBC-broad search and is $\sim 1.1 - 12.6$ times more sensitive than the PyCBC-BBH search at a false alarm rate threshold of 1 in 100 years.

We also compare our search against two other searches, namely cWB and GstLAL-IMBH, that were used by the LIGO Scientific, Virgo & Kagra collaboration (LVK) to look for IMBH binaries in O3 run.[15] For this purpose, we utilise the results of the injection campaign that were used by the LVK to place upper limits on the merger rate density for a discrete set of IMBH binaries. The dataset is publicly

Table 1. Summary of the single pipeline sensitive volume-time $\langle VT \rangle$. Here, M_T is the total source frame mass of the binary and $q = m_2/m_1 \leq 1$ denotes the mass ratio of the binary. $\chi_{\rm eff}$ is the mass-weighted combination of the spins parallel to the orbital angular momentum $\vec{L}$ while $\chi_{\rm p}$ captures the average amount of precession exhibited by a generically precessing system over many cycles defined at reference frequency of 11 Hz during the inspiral.

M_T ($M_\odot$)	q	$\chi_{\rm eff}$	$\chi_{\rm p}$	$\langle VT \rangle_{\rm PyCBC}$[Gpc^{3}yr]	$\langle VT \rangle_{\rm cWB}$[Gpc^{3}yr]	$\langle VT \rangle_{\rm GstLAL}$ [Gpc^{3}yr]

available at `https://dcc.ligo.org/LIGO-P2100179/public`, and it contains details about the parameters of each of the injections and also their associated p-value as reported by the contributing searches. The signals themselves were numerically simulated and are designed to imitate GWs from a representative population of IMBH binaries with generic spins. Additional details about the injections can be found in.[15]

To estimate $\langle VT \rangle$ using the publicly available dataset, we start off by calculating the number of signals that are recovered by each of three contributing searches. We do this by considering only those injections whose p-value is less than the minimum p-value of the loudest noise trigger, namely that of 200214_224526 in the.[15] This trigger has a minimum p-value of 9.2×10^{-2} and was only reported by the weakly model-dependent cWB search. The $\langle VT \rangle$ is then given by

$$\langle VT \rangle = \frac{N_{\rm rec}}{N_{\rm total}} \langle VT \rangle_{\rm total} \tag{1}$$

where the first term denotes the fraction of injections that are recovered below the p-value threshold while the second term denotes the total spacetime volume covered by a given injection set.

We tabulate the results of this analysis for each of the three pipelines for each simulated IMBH binary in Table 1. Amplitude and phase errors arising from detector calibration have not been included in the analysis, but a statistical uncertainty of 4%-7% is expected. We find that the PyCBC-IMBH search has higher sensitivity as compared to the GstLAL-IMBH for all of the mass bins and is comparably sensitive (if not better for most of the symmetric and/or relatively low total mass bins) to cWB search.

The latter can be understood as follows. As discussed in Sec. 2, the PyCBC-IMBH search uses only the dominant multipole templates in matched filtering. Hence, the sensitivity drops with a decrease in mass ratio as compared to the cWB search. This is because a decrement in mass ratio corresponds to an increase in the contribution coming from the sub-dominant harmonics. The cWB search being a weakly modelled search, is oblivious to this effect and hence has higher sensitivity than template-based searches. Furthermore, if one compares the sensitivity of a given search for a given total mass but decreasing mass ratio, one will observe that the search performance degrades owing to an overall decrease in the intrinsic luminosity of the system involved.

Concerning the total mass of a binary, the PyCBC search tends to have higher sensitivity for relatively lower total mass as signals from such systems tend to have a longer inspiral within the detector bandwidth, thus allowing for a larger SNR. At higher total mass, the cWB search has higher sensitivity because of its efficient signal-noise discriminators, which allow it to distinguish the signal from noisy transients better, thus allowing for a relatively lower p-value and hence greater sensitivity. This also explains why the PyCBC search has a poorer performance for a system with a given mass distribution but having a relatively anti-aligned spin.

GW signals from a significantly precessing binary can have a notably suppressed inspiral right before the merger, causing a characteristic sine-Gaussian morphology. The search summarised here uses non-precessing quadrupolar templates meaning the SNR recovered would be lower and the χ^2_r higher owing to mismatch with templates.

4. Conclusion

Here, we summarise the salient features of the optimisation made to the existing PyCBC search to target short-duration GWs from massive BBHs. This optimisation enabled us to improve the search performance and re-detect the event GW190521 with improved statistical significance. We also compare the sensitivity of PyCBC-IMBH with other searches used for the detection of IMBH binaries using the public data.

Detection of IMBH and its subsequent studies has the potential to provide valuable insight into the BBH population. Hence searches like this are going to be increasingly important. While we are primarily concerned here with detection of IMBH binaries, this type of search can be used to detect highly red-shifted BBHs which we expect to see in the next few years with the advent of third-generation GW observatories like the Einstein Telescope and Cosmic Explorer. Thus, the future of this field is quite exciting!

Acknowledgments

KC is extremely grateful to the organisers of the conference for hosting such a wonderful meeting in challenging circumstances. We thank Gayathri V. and Keith Riles for their comments on an earlier draft of this proceeding. The authors are grateful for the computational resources and data provided by the LIGO Laboratory which is funded by National Science Foundation Grants No. PHY-0757058 and No. PHY-0823459. The open data is available in the Gravitational Wave Open Science Center (https://www.gw-openscience.org/), a service of LIGO Laboratory, the LIGO Scientific Collaboration and the Virgo Collaboration. The authors also acknowledge the use of the IUCAA LDG cluster, Sarathi, for computational/numerical work. KC acknowledges the MHRD, Government of India, for the fellowship support. AP's research is supported by SERB-Power-fellowship grant SPF/2021/000036, DST, India. VVO and TD acknowledge financial support from Xunta de Galicia (Centro singular de investigación de Galicia accreditation 2019-2022), by European Union ERDF, and by the "María de Maeztu" Units of Excellence program MDM-2016-0692 and the Spanish Research State Agency. GSCD and IWH acknowledge the STFC for funding through grant ST/T000333/1. CM was supported by the STFC through the DISCnet Centre for Doctoral Training. KS acknowledges the Inter-University Centre of Astronomy and Astrophysics (IUCAA), India, for the fellowship support.

We want to thank all of the essential workers who put their health at risk during this ongoing COVID-19 pandemic. Without their support, we would not have completed this work. We offer condolences to people who have lost their family members during this pandemic.

Matter shells modifying gravitational wave signals

Monos Naidoo*, Nigel T. Bishop and Petrus J. van der Walt

Department of Mathematics, Rhodes University, Grahamstown, 6140, South Africa

www.ru.ac.za

As detections of mergers of compact bodies begin to flow in, and as we enter an era of precision GW measurements, our understanding of compact bodies, their physics and that of the surrounding astrophysical environment, will continue to grow and at times even be challenged. The need to revise the mass bounds of compact bodies such as BHs and NSs and the possibility of the existence of GW echoes are just some of consequences of the first few years of GW detection. In previous work, using linearised perturbation theory, we made the novel finding that a dust shell will cause a GW to be modified both in magnitude and phase, but without any energy being transferred to or from the dust. We extend our analysis to matter shells surrounding compact body mergers and to intervening matter in cosmology. Instead of only monochromatic GW sources, as we used in our initial investigation, we also consider burst-like GW sources. The thin density shell approach is modified to include thick shells by considering concentric thin shells and integrating. Solutions are then found for these burst-like GW sources using Fourier transforms. In the context of cosmology, apart from the gravitational redshift, the effects are too small to be measurable. We show that GW echoes that are claimed to be present in the LIGO data of certain events, could not have been caused by a matter shell. We do find, however, that matter shells surrounding BBH mergers, BNS mergers, and CCSNe could make modifications of order a few percent to a GW signal. These modifications are expected to be measurable in GW data with current detectors if the event is close enough and at a detectable frequency; or in future detectors with increased frequency range and amplitude sensitivity.

Keywords: Gravitational waves; Gravitational wave echoes; Bondi-Sachs; Matter shell; Linearized perturbation theory.

1. Introduction

Claims have been made that echoes have been detected in the LIGO data of the binary black hole (BBH) merger GW150914,[1,2] and also from the binary neutron star (BNS) merger GW170917.[3] It has been postulated that various exotic compact objects (ECOs) may cause echoes in a gravitational wave (GW) signal and that these may be the cause of the echoes claimed to be observed. These claims have been contested,[4,5] sparking a debate and responses in defense of the claims[6,7] with further substantiations.[3,8] A number of ECO scenarios have been investigated. At the quantum level, Hawking's information paradox suggests Planck-scale modifications of black hole horizons (firewalls[9]) and other modifications to black hole structure (fuzzballs[10]). Dark matter particles have been suggested surrounding star-like objects.[11] Other postulates include stars with interiors consisting of self-repulsive, de Sitter spacetime, surrounded by a shell of ordinary matter (gravastars[12]). Then

there are Boson stars, which are macroscopic objects made up of scalar fields.[13] All these objects are compact bodies mimicking black holes, but without a horizon. One consequence of these horizonless structures is that ingoing gravitational waves produced in a merger may reflect multiple times off effective radial potential barriers. The gravitational waves may be, in effect, trapped between effective radial potential barriers causing the waves to be 'bounced' off these barriers several times with wave packets leaking out to infinity at regular times. These gravitational wave signals, 'trailing' the main (outward bound) signal are referred to as gravitational wave echoes.[14–16]

Whilst much of the discussion around gravitational wave echoes has been within the context of 'new physics'[17–23] (beginning with[14]), the possibility that the echoes may be a consequence of the astrophysical environment should also be investigated. One such scenario is the effect of a matter shell surrounding the gravitational wave source. This case was considered using numerical methods in,[24] and was also mentioned in our previous work on the effects of matter on GW propagation.[25]

Echoes from the astrophysical environment were considered in,[26] by placing a massive shell that is not infinitely thin. This was a generalisation of the approach of[27] which was based on an infinitely thin shell. As we have shown in our paper[25] the case for a thin shell can be generalised to that of a thick shell by considering several concentric thin shells and integrating[26] showed that the deviation from Schwarzschild ringdown in their astrophysical estimations were relatively small except for a large mass which indicated that for the majority of astrophysical scenarios the effect would be relatively small. However they did note that considerations of dark matter around black holes (or compact body mergers) would leave some parametric freedom for echoes as well,[24] studied both the combination of contributions of modifications of the Schwarzschild geometry near the surface, and a nonthin shell of matter surrounding the compact body/merger. They found that a massive shell at a distance could be distinguished from the purely Schwarzschild evolution of perturbations. However, for the situation of new physics near the surface of a compact object, (a wormhole in their case), the strong echoes of the surface dominate the echoes of the distant shell. Furthermore, they found that it would take an extraordinarily large mass, located sufficiently close to the wormhole, to lead to discernable changes in the main echoes of the surface and that these changes would be relatively small. The interaction of GWs with matter has also been studied in cosmology,[28,29] with the objective of using GW observations to constrain the properties of dark matter.

In previous work,[25] we showed that a thin spherical dust shell surrounding a gravitational wave source, causes the gravitational wave to be modified both in magnitude and phase, but without any energy being transferred to or from the dust. That work suggests the possibilty of GW echoes. In Sec. 2 we describe the problem considered in this scenario, the assumptions made and the key results.

The solution of[25] is for a monchromatic GW source. A general waveform may be decomposed into a sum of Fourier components, and the technical details are given

in Sec. 3. The decomposition is implemented within a Matlab script using the Fast Fourier Transform, and validation results are reported in this section.

Secs. 4 and 5 are about the astrophysics of the various scenarios considered. In[30] we investigated whether a matter shell could explain the echoes that may exist in the LIGO data of GW150914 and GW170817. It was found that the shell would need to have such a large mass that it would constitute a black hole and this is discussed in Sec. 4. Our results show that if GW echoes are confirmed in another GW event, and with a relative magnitude and delay time similar to that of GW150914 and GW170817, then a matter shell would not be a viable explanation, so strengthening the case that an ECO would have been observed.

A key factor in determining the echo properties of a matter shell is the echo delay time, which in the cases above was of order 1s. If the echo delay time is much smaller, order 1ms or smaller, then shell properties that are physically acceptable could lead to measurable effects; however, the short delay time would mean that the effect would not appear as an echo in the usual sense, but rather as a modification to the original signal. Examples of such signal modifications are given in Sec. 5.1 for a matter shell around an event like GW150914; in Sec. 5.2 for black hole quasinormal mode signal following a binary neutron star merger; and in Sec. 5.3 for the case of core collapse supernovae (CCSNe).

Our conclusions are discussed in Sec. 6.

2. Effect of a shell of matter on a GW

In[25] we considered the scenario of a thin shell of matter surrounding a gravitational wave source such as a compact binary merger, as shown schematically in Fig. 1. The spacetime around the GW source in[25] would be otherwise empty except for the surrounding shell of matter. Confining the investigation to a thin shell does not preclude the case of a thick shell. Results can easily be applied to a series of concentric thin shells and then integrated to give the effect for a thick matter shell. The EOS is taken, as a start, to be that of dust. The results show that the shell modifies the outgoing GWs in both phase and magnitude without contradicting previous results about energy transfer. The problem is set up within the Bondi-Sachs formalism for the Einstein equations with coordinates based on outgoing null hypersurfaces.[31,32] The null hypersurfaces, are labelled by the coordinate $x^0 = u$, the angular coordinates by x^A $(A = 2, 3)$ and the surface area radial coordinate by $x^1 = r$. The angular coordinates (e.g. spherical polars (θ, ϕ)) label the null ray generators of a hypersurface $u =$ constant. The Bondi-Sachs metric then describes a general spacetime, which may be written as

$$ds^2 = -\left(e^{2\beta}\left(1+\frac{W}{r}\right) - r^2 h_{AB}U^A U^B\right)du^2 - 2e^{2\beta}dudr \\ - 2r^2 h_{AB}U^B dudx^A + r^2 h_{AB}dx^A dx^B\,, \tag{1}$$

where, $h^{AB}h_{BC} = \delta^A_C$. The condition that r is a surface area coordinate implies $\det(h_{AB}) = \det(q_{AB})$, where, q_{AB} is a unit sphere metric (e.g. $d\theta^2 + \sin^2\theta d\phi^2$).

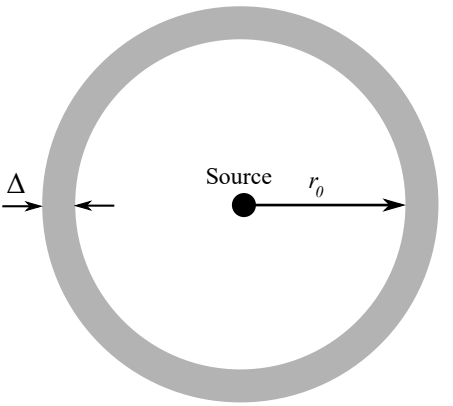

Fig. 1. The problem of a GW source which is surrounded by a spherical shell of mass M_S located between $r = r_0$ and $r = r_0 + \Delta$, where r is the distance from the source.

The GW strain far from the source is written $\mathcal{H}_{M0} = r(h_+ + ih_\times)$, where $h_+, ih_\times$ are the usual polarization modes in the TT gauge. Now suppose that, in the absence of the matter shell,

$$\mathcal{H}_{M0} = \Re(H_{M0}\exp(2i\pi f u))\,{}_2Z_{2,2}\,, \tag{2}$$

where f is the frequency (assumed to be monochromatic) of the GWs; H_{M0} is a constant determined by the physics of the GW source; and ${}_2Z_{2,2}$ is a spin-weighted spherical harmonic related to the usual ${}_sY_{\ell,m}$ as specified in.[33,34] Then, as found in,[25] the introduction of a spherical shell around the GW source of mass M_S, radius r_0 and thickness Δ modifies the wave strain to:

$$\mathcal{H} = \Re\left(H_{M0}\left(1 + \frac{2M_S}{r_0} + \frac{iM_S}{\pi r_0^2 f} + \frac{iM_S e^{-4i\pi r_0 f}}{4\pi r_0^2 f} + \mathcal{O}\left(\frac{M_S\Delta}{r_0^2}, \frac{M_S}{r_0^3 f^2}\right)\right)\exp(2i\pi f u)\right)\,{}_2Z_{2,2}\,. \tag{3}$$

Each of the terms containing M_S in Eq. (3) represents a correction to the wave strain in the absence of the shell.[25] The first correction, $2M_S/r_0$, is part of the gravitational red-shift effect, the main consequence of which is a reduction in the frequency; this effect is well-known, and henceforth we will assume that GW waveforms to be considered have allowed for this effect. The second term, $iM_S/(\pi r_0^2 f)$, is out of phase with the leading terms $1 + 2M_S/r_0$ and hence represents a phase shift of the GW. This term, to $\mathcal{O}(M_S)$, does not change the magnitude of $\mathcal{H}$ and hence has no effect on the energy of the GW. The presence of $e^{-4\pi i r_0 f}$ in the third term

describes a change in the magnitude of $\mathcal{H}$, as verified in.[25] In this context, the modified signal would then be interpreted as an echo of the main signal. The echo varies from the main signal in both magnitude and phase, with the magnitude of the echo described by

$$R = \frac{M_S}{4\pi r_0^2 f} \tag{4}$$

relative to the original signal.

3. Solution for a burst-like GW source using Fourier transforms

The time-delay of the echo is $2r_0$, but the echo's magnitude depends on the wave frequency f. The GW sources reported to date are not monochromatic but are burst-like. Such a source may be decomposed into its Fourier components and Eq. (3) applied to each component, and the echo signal obtained by summing over the transformed components. Because the magnitude of the transformation is frequency-dependent, the echo signal will have a form more complicated than simply a time-delay and magnitude change to the original signal. This effect is now analyzed.

We replace $\Re(H_{M0}\exp(2i\pi f u))$ in Eq. (2) by $h(u)$ defined in the interval $u_0 \leq u \leq u_{N-1}$; and then construct a discrete representation of $h(u)$, $h_k = h(u_k)$ ($k = 0, \cdots, N-1$), with the u_k on a regular grid, i.e. $u_{k+1} - u_k = \delta$ for $k = 0, \cdots, N-2$. Note that if the highest frequency that needs to be resolved is f_m, then N should be chosen so that $(u_{N-1} - u_0)/(N-1) < 1/(2f_m)$, i.e. to satisfy the Nyquist condition. The discrete Fourier transform[35] of $\{h_k\}$ is

$$H_n = \sum_{k=0}^{N-1} h_k \exp\left(\frac{2\pi i k n}{N}\right) \quad \text{with inverse} \quad h_k = \frac{1}{N}\sum_{n=0}^{N-1} H_n \exp\left(\frac{-2\pi i k n}{N}\right). \tag{5}$$

Then defining $H_{2,n}$ and $H_{3,n}$ to be coefficients in the transform domain of the second (phase-shift) and third (echo) terms of Eq. (3), we have

$$\begin{aligned}
&H_{2,n} = \frac{iM_S H_n}{\pi r_0^2 f_n}\,, \quad H_{3,n} = \frac{iM_S H_n \exp(-4\pi i r_0 f_n)}{4\pi r_0^2 f_n}\,, \quad n = 1, \cdots, \frac{N}{2}\,,\\
&H_{2,n} = H^*_{2,N-n}\,, \quad H_{3,n} = H^*_{3,N-n}\,, \quad n = \frac{N}{2}+1, \cdots, N-1\,,\\
&H_{2,0} = H_{3,0} = 0\,,
\end{aligned} \tag{6}$$

where * denotes the complex conjugate, and where we have used the condition that, in the time domain, all quantities are real. It is being assumed that N is even, and normally $N = 2^m$ (with m an integer) for convenience when using the fast Fourier transform; further

$$f_n = \frac{n(N-1)}{N(u_{N-1} - u_0)}\,. \tag{7}$$

Then $h_{2,k}, h_{3,k}$ are found on applying the inverse discrete Fourier transformation.

A Matlab script that implements the calculation of the previous paragraph is available as Supplementary Material in.[30] The script was checked by applying it to a monochromatic signal $h(u) = \Re(-i\exp(2\pi i f u))$. The errors $e_{2,k}$ in $h_{2,k}$ and $e_{3,k}$ in $h_{3,k}$ are

$$\begin{aligned} e_{2,k} &= \left| h_{2,k} - \Re\left(iM_S/(\pi r_0^2 f)\exp(2i\pi f u)\right)\right| \\ e_{3,k} &= \left| h_{3,k} - \Re\left(iM_S/(4\pi r_0^2 f) e^{-4\pi i r_0 f}\exp(2i\pi f u)\right)\right| . \end{aligned} \tag{8}$$

For the case $u_0 = 0$ms, $u_{N-1} = 100$ms, $f = 1$kHz, $r_0 = 1.25$ms ($\approx$km), and $M_S = 0.25$ms ($\approx M_\odot$), we found:

N	$\|\|e_{2,k}\|\|$	$\|\|e_{3,k}\|\|$
2^9	4.0×10^{-4}	1.6×10^{-3}
2^{15}	1.6×10^{-6}	2.7×10^{-5}
2^{21}	2.4×10^{-8}	4.3×10^{-7}

(9)

where $||e_k||$ is defined to be

$$||e_k|| = \sqrt{\frac{\sum_{k=0}^{N-1} e_k^2}{N}} . \tag{10}$$

Thus the errors are tending to zero, and N can be chosen so as to attain a desired accuracy. Note that an error of order machine precision is achieved for special values of the frequency $f = k(N-1)/N/(u_{N-1} - u_0)$ with k an integer; in this case we would have that the cyclic assumption of the discrete Fourier transform would be satisfied, i.e. $u_i = u_{i+N}$.

4. Could matter shells explain the GW echo claims?

In,[1] the first of the tentative search for echoes, the authors find evidence for the existence of echoes in the first detection event[36] **GW150914**. They find further comparable evidence for echoes from the events GW151012[37] (then referred to as LVT151012) and GW151226.[38] The references report a number of echo events for GW150914, with the first occurring at about 0.3s after merger; therefore, if caused by a matter shell, the radius would be about 45,000km. The magnitude of the echo was about 0.0992 times that of the original signal. Using 132Hz for the frequency, which is its value when the amplitude was at its maximum at the end of the merger phase, and applying Eq. (4) gives $M_S \simeq 740{,}000 M_\odot$. Such a mass within a radius of 45,000km would constitute a black hole, so the scenario of an echo caused by a shell can be discounted for GW150914.

Extending their investigations to the first BNS detection **GW170817**,[39] the authors of[1] find evidence again of the existence of echoes in the postmerger event.[3] The echo was reported to occur at frequency $f_{echo} \simeq 72$ Hz, approximately 1.0 sec after the BNS merger event. The inspiral signal is at 72Hz about 4.0s before merger, so if the reported echo is caused by a matter shell it must have a radius of about

2.5s$\simeq$ 750,000km. Assuming that the magnitude of the echo signal must be at least 0.01$\times$ that of the original signal and applying Eq. (4), it follows that for the echo to be caused by a shell it would have a mass of approximately $10^7 M_\odot$. Now, a mass of $10^7 M_\odot$ inside a radius of 750,000km would constitute a black hole, so the scenario of an echo caused by a shell can be discounted for GW170817.

The above two examples illustrate the general difficulty of producing a GW echo by means of a matter shell. An echo, in the usual sense, is a repeat of the original signal after a short time delay, which in practice must be at least hundreds of ms, corresponding to a shell radius of at least $\sim$ 20,000km. Now, Eq. (4) shows that the shell mass $M_S = 4\pi R r_0^2 f$ which, for expected values of the frequency f, will be large – either implying a black hole and thus not feasible, or requiring an unexpected astrohysical scenario. A much smaller shell radius would avoid these difficulties, but the effect of the shell would be seen as a modification of the original signal, rather than as an echo. Some possible scenarios are presented in the next section.

5. GW events and matter shells

5.1. *GW150914 in the presence of a matter shell*

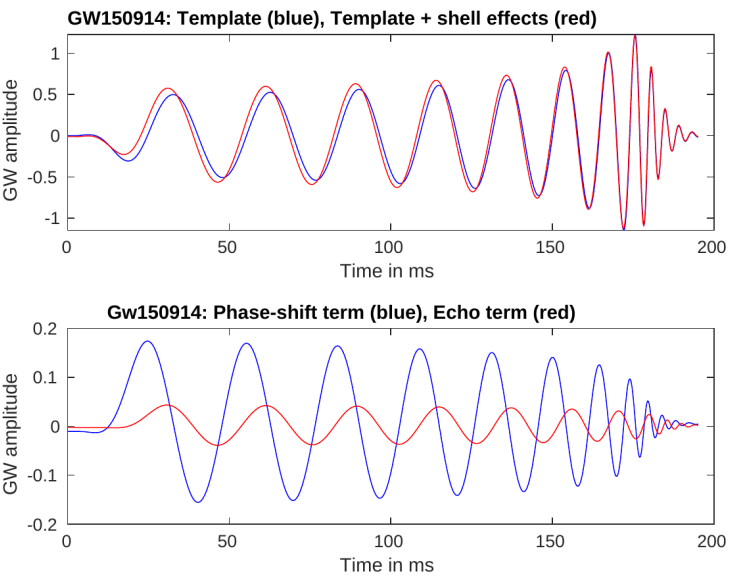

Fig. 2. The effect of a matter shell of radius 3ms (about 900km) and mass 0.3ms (about $60 M_\odot$) on the signal of GW150914. The top panel shows the original signal in blue, and the original signal plus modifications due to the shell in red. The lower panel shows the modifications due to the phase-shift term in blue, and due to the echo term in red.

Although a matter shell could not explain the echoes that might exist in GW150914 data, we now investigate how a hypothetical matter shell might modify the signal from a binary black hole merger. We consider the example case of a shell at radius 3ms (about 900km) and of mass 0.3ms (about $60M_\odot$) and the signal of GW150914[40–42] (Of course, the astrophysical evidence does not suggest the existence of such a shell). The results are shown in Fig. 2. The top panel shows that there is a small but noticeable modification to the template signal, particularly at early times; this is because the frequency is lower at early times and so the modification effects are larger. The bottom panel shows the contributions of the phase-shift term (h_2, blue) and the echo term (h_3, red); it is noticeable that, unlike the template signal, these terms decrease in magnitude as the frequency increases with time.

The accuracy of the results presented in Fig. 2 is limited since the formalism used in[25] assumed a weak field GW source, which is not the case for two black holes at merger. In particular, GWs reflected by the shell would be partially absorbed by the black holes, so reducing the magnitude of the echo contribution to the GW signal.

5.2. *Binary Neutron Star (BNS) mergers*

BNS GW events that have been observed include GW170817[43] and GW190425.[44] Of these, GW170817 was at a higher signal to noise ratio and the event was observed post-merger in the electromagnetic spectrum,[45] indicating that the post-merger object contained a large amount of free matter; we will therefore focus on this event.

The relevant source parameters reported for the event are[46,47]: total mass $M_1 + M_2 = 2.74M_\odot$, and radii $R_1 = 10.8$km, $R_2 = 10.7$km. The reported GW signal increased in amplitude and frequency until 500Hz, at which stage the signal finished; i.e. the signal was observed during the inspiral phase, but ended as the two objects started to merge. The merger probably produced a central remnant of a neutron star or a black hole, in which case GWs in the lowest quasinormal mode would have been produced; however, the frequency of these GWs would be about 1.5 to 3kHz for a neutron star, or about 6kHz for a $2M_\odot$ black hole, which is outside the sensitivity band of the LIGO detectors.

In order to estimate the possible effect of matter on GWs emitted from a central remnant, we consider the model of a spherical shell of mass $M_S = 0.7M_\odot$ and radius $r_0 = 25$km around a GW source at either 6kHz or 2kHz. We find that the phase-shift term $2iM_S/(r_0^2\nu)$ evaluates to

$$\frac{iM_S}{r_0^2\pi f} = 0.0263i \;\text{ or }\; 0.0788i\,, \tag{11}$$

for 6kHz or 2kHz, respectively. The echo effect would be 1/4 of the above values, and the delay would be 0.1667ms, which is the same as the wave period (at 6kHz),

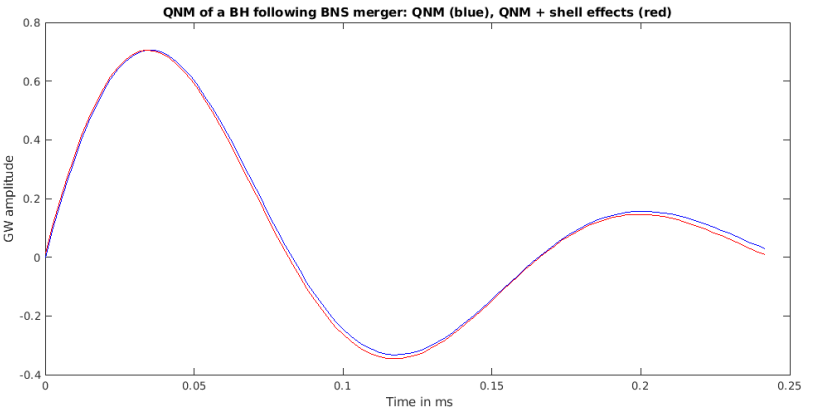

Fig. 3. The effect of a matter shell of radius 25km and mass $0.7M_{\odot}$ on a quasinormal mode (QNM) signal of a $2M_{\odot}$ remnant of a binary neutron star merger. The original signal is in blue, and the original signal plus modifications due to the shell is in red.

or less than a wave period (at 2kHz). Thus, in the future if GW detectors in the kHz band are operational and if a BNS event occurs at high signal to noise ratio, then shell effects would affect the GW signal in a measurable way, although the small delay time means that it would be difficult to disentangle the echo and phase-shift effects from the main signal. The modifications to the quasinormal mode signal are illustrated in Fig. 3. However, there are a number of caveats that should be noted:

- The model in[25] assumed that the shell is static, but the aftermath of a BNS meger will be highly dynamical.
- The hypothesis of a shell forming is not supported by a detailed numerical simulation; indeed, since the system started as an inspiral, the matter outside the remnant should have a ring-like structure. Thus, the matter effects could be much smaller than shown in Eq. (11) for an observer on the axis of rotation of the system.
- The comment at the end of Sec. 5.1 about absorption of GWs by a black hole applies here.

So the quantitative values in Eq. (11) should be interpreted as indicative of the order of magnitude of the interaction of GWs with matter, rather than as precise estimates. It should also be noted that if the numerical modeling includes all the matter, and if the simulation run period includes the quasinormal mode ringdown, then shell effects would already be included in the simulation.

5.3. *Core collapse supernovae*

We next turn our attention to an anticipated candidate of detectable GW waves: core collapse supernovae (CCSNe). Whilst BBH and BNS mergers are currently

the only GW events picked up by LIGO and VIRGO, supernovae are expected to produce, under certain conditions, GW waves detectable by the current generation of interferometers or those on the horizon. For now, all detection of supernovae have been confined to electromagnetic detection. Photons originate at the outer edge of a star and hence provide only limited information on the interior regions. The detection of GWs which are the result of the aspherical motion of the inner regions will provide a wealth of information on these regions and the mechanism leading to the supernova explosion, where all the four fundamental forces of nature are involved.

Whilst the central engines and inner regions of CCSNe have yet to be fully understood, there exist several studies of their progenitors and the subsequent evolution and detection.[48–51] For stars of mass larger than $8M_\odot$, evolution normally proceeds through several stages of core burning and then to core collapse once nuclear fusion halts when there are no further burning processes to balance the gravitational attraction. Typically, these cores are iron cores, with the critical mass signalling the onset of core collapse ranging from $1.3M_\odot$ to $1.7M_\odot$. The core breaks into two during the collapse, with the inner core of $0.4M_\odot$ to $0.6M_\odot$ in sonic contact and collapsing homologously and the outer core collapsing supersonically. The inner core reaches supranuclear densities of $\sim 2\times 10^{14}\mathrm{g/cm}^3$ where the nuclear matter stiffens, resulting in a bounce of the inner core. The resulting shock wave is launched into the collapsing outer core. However, the shock loses energy to dissociation of iron nuclei, stalling at ∼150 km within ∼10 ms after formation. Many computationally demanding simulations exist[52–54] for generation of GWs from CCSNe.

5.3.1. *Model for the GW modifications due to matter around the inner core*

Ref.[54] presents GW waveforms from simulations of CCSNe for various zero age main sequence (ZAMS) masses in the range $9M_\odot, \cdots, 60M_\odot$. The GW signal starts with an initial burst of duration about 50ms and frequency about 100Hz, followed by a quiescent period. We model this part of the waveform as

$$\begin{aligned} &h_+ + ih_\times \sim \sin(0.2\pi u)\sin(0.02\pi u)\,{}_2Z_{2,2}\,, \quad 0\le u\le 50\\ &h_+ + ih_\times = 0\,, \quad 50\le u\le 100\,. \end{aligned} \tag{12}$$

GWs are generated by aspherical motions in the inner core, commencing just after the bounce. The inner core is surrounded by the outer core, treated as a thick matter shell, and we now model its modifications to the GW signal. The shell has an inner radius r_{in}, an outer radius r_{out}, and density at $r = r_{in}$ of ρ_0 with density fall-off $\rho \propto r^{-1-a}$ with $1/2 \le a \le 2$. The effect of the whole shell is obtained by decomposing it into thin shells and then integrating. The result for the echo term is not a simple analytic expression and will be evaluated numerically. However, the phase shift term does give a simple analytic result

$$\int_{r_{in}}^{r_{out}} \frac{iM_s}{r^2\pi f}dr = i\int_{r_{in}}^{r_{out}} \frac{4\pi r^2\rho_0(r_{in})^{1+a}}{r^{1+a}r^2\pi f}dr = \frac{4i\rho_0 r_{in}}{af}\left(1-\left(\frac{r_{in}}{r_{out}}\right)^a\right), \tag{13}$$

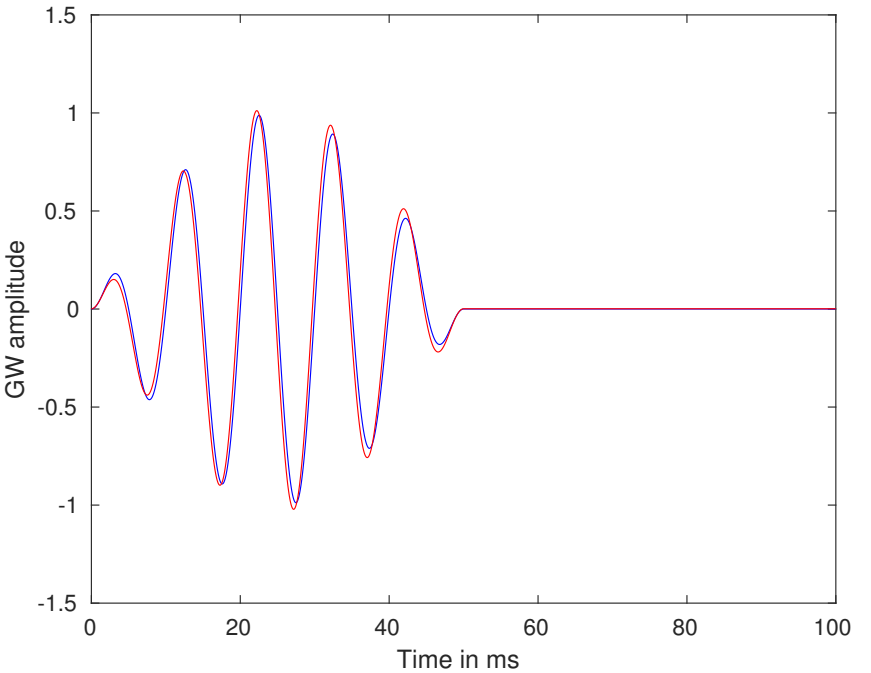

Fig. 4. The effect on the initial burst in a CCSNe GW signal of a matter shell extending from a radius 30km to the shock boundary at 150km. The original signal is in blue, and the signal plus modifications is shown in red.

where f is the GW frequency. Fig. 4 shows the original signal given by Eq. (12) in blue, and the original signal plus shell modifications in red, for the case $r_{in} = 0.1$ms (≈ 30km), $r_{out} = 0.5$ms (≈ 150km), $a = 1$, and $\rho_0 = 0.05/\text{ms}^2$ ($\approx 0.75{\times}10^{12}\text{g/cm}^3$). These values model: the inner core as a proto-neutron star (PNS) of radius 30km, and whose oscillations generate the GWs; the shock boundary as having a radius of 150km; and the density at the inner radius ($\approx 0.75 \times 10^{12}\text{g/cm}^3$) at a couple of orders below the supranuclear density. For this model, Eq. (13) evaluates to $0.16i$, and the total mass of the shell to $0.503M_\odot$.

There is some uncertainty in the parameter values that should be used in modeling the matter shell around the inner core. The simple form of Eq. (13) shows how varying the parameters would change the magnitude of the shell effect.

6. Conclusion

There are astrophysical scenarios which can be regarded as comprising a shell of matter around a GW source, and this paper has investigated in what way the GW signal would be affected. The investigation started with GW events for which echoes have been claimed to exist in the LIGO data, and it was found that such echoes

could not be caused by a matter shell. Thus, an unambiguous observation of GW echoes in the future would favour the existence of ECOs.

We investigated the effect of matter shells in three specific example cases. The first was a binary black hole merger analogous to GW150914, surrounded by a hypothetical matter shell at radius 900km and mass $60M_{\odot}$. Astrophysically, such a shell is highly unlikely to exist, but this case is useful as it well illustrates some of the features of the shell effects on the waveform. The next case considered was the quasinormal mode signal from the remnant of a binary neutron star merger like GW170917. In this case, it is known that there is a substantial amount of matter around the remnant, although the extent to which the shell model is appropriate is unclear. The final case considered was that of a core collapse supernova. Although GWs from such events have not been observed, they are regarded as potential sources; and here it is clear that the proto neutron star, in which the GWs are generated, is surrounded by shells of matter. Of the three cases, the core collapse supernova is that which yielded the largest shell modifications to the GWs, and for which the predictions are most reliable.

The effects of matter shells are small but measurable if the signal to noise ratio is sufficiently high. As GW observations become more accurate, through both hardware developments and, as time passes, the increasing chance of observing nearby events, these effects will need to be taken into account.

We consider gravitational radiation in the presence of non-compact extra dimensions. If their number is odd, all spacetime becomes odd-dimensional and formation of gravitational radiation becomes non-trivial because of violation of the Huygens principle. Gravitational waves travel with the speed of light, while the full retarded gravitational field of a localized source propagates with all velocities lower or equal to the speed of light, so special care is needed to extract radiation. Here we consider a simplified model consisting of two point masses moving on a three-brane embedded in five-dimensional bulk. Particles are assumed to interact through a massless scalar field living on the same brane, while gravitational radiation is emitted into the full five-dimensional space. We use the Rohrlich-Teitelboim approach to radiation, extracting the radiative component of the retarded gravitational field via splitting of the energy-momentum tensor. The source term consists of the local contribution from the particles and the non-local contribution from the scalar field stresses. The latter is computed using the DIRE approach to the post-Newtonian expansions. In the non-relativistic limit, we find an analog of the quadrupole formula containing the integral over the full history of motion, preceding the retarded moment of time. We compute gravitational radiation and study the orbit evolution of the non-relativistic circular binary system on the brane.

Keywords: Extra dimensions, Huygens principle, gravitational radiation, brane

1. Introduction

Gravitational radiation in the higher-dimensional spacetimes has become an intriguing problem in the last twenty years due to development of the gravity theories with large extra dimensions.[1–4] Recent successes of the gravitational-wave astronomy give us the new tool for exploring extra dimensions.[5–10] Some constraints on their size, number and geometry have already been extracted.[11–16] Another new tool relevant to extra dimensions is shadow of a black hole.[17–19]

With regard to the theoretical study of multidimensional radiation, then in the majority of literary sources only radiation in even space-time dimensions is studied,[20–24] while the odd dimensions were discussed mainly in the more academic context of the problem of radiation reaction.[25–28] Huygens principle violation in odd dimensions[29–31] leads to significant difference of field propagation in even and odd dimensions. In both cases, signal from the instantaneous flash reaches the observation point in time required to propagate with the speed of light. However,

in odd dimensions, after the arrival of the primary signal an endless tail is observed which is not the case in the even dimensions. Mathematically, this is related to the localisation of the odd-dimensional retarded Green's functions not only on the light cone, but also inside it:

$$G^{2\nu+1}_{\rm ret}(x) = \frac{(-1)^\nu}{(2\pi)^\nu}\frac{d^{\nu-1}}{(rdr)^{\nu-1}}\frac{\theta(t)\,\theta(t^2-r^2)}{\sqrt{t^2-r^2}},\ \nu\in\mathbb{N}, \tag{1}$$

where $t = x^0$, and $r = |\mathbf{x}|$. The odd-dimensional gravitational radiation of the non-relativistic binary systems has been studied[32] using the effective field theory formalism,[33,34] which is insensitive to the dimensionality of spacetime. But since it is based on the Fourier decompositions, the obtained analog of the quadrupole formula does not contain any information about the gravitational field in the wave zone and does not reveal the role of the tail in the formation of the gravitational-wave signal. So here we consider five-dimensional radiation essentially using the space-time picture.

2. The setup

We consider a simplified model of a binary system whose motion is confined inside the four-dimensional subspace (brane). Particles interact with each other only through the massless scalar field localised on the same brane, while gravitational radiation is five-dimensional. Our localisation mechanism is purely kinematical: if the initial conditions are restricted to the brane, and the mediator scalar field is four-dimensional, the system remains in the brane forever. Such a system admits the stable elliptical orbits, and the interaction field is free from tails, providing us with a simple setup to study the features of the odd-dimensional gravitational radiation related to the Huygens principle violation.

Gravitational radiation of such a system can be described by the linearised theory on the Minkowski background without use of the quadratic part of the Ricci tensor corresponding to the gravitational stresses.[35] However, one still needs to take into account the scalar field stresses corresponding to the energy of the particles interaction:

$$\Box\bar{h}_{MN}(x) = -2\kappa_5\left[T^{\rm P}_{MN}(x)+T^{\rm F}_{MN}(x)\right],\quad \partial^M\bar{h}_{MN}=0, \tag{2}$$

$$T^{\rm P}_{MN}(x) = \delta^\mu_M\delta^\nu_N\sum_{a=1}^{2}m_a\int d\tau_a\,\dot{z}_{a\mu}\dot{z}_{a\nu}\,\delta^{(4)}(x-z_a)\delta(x^4), \tag{3}$$

$$T^{\rm F}_{MN}(x) = \frac{1}{4\pi}\delta^\mu_M\delta^\nu_N\left(\partial_\mu\varphi\partial_\nu\varphi-\frac{1}{2}\eta_{\mu\nu}\partial^\alpha\varphi\partial_\alpha\varphi\right)\delta(x^4), \tag{4}$$

where $M,N=\overline{0,4}$ and $\mu,\nu=\overline{0,3}$, and $\eta_{MN}=\mathrm{diag}(-1,1,1,1,1)$. Here, $z^\mu_a(\tau_a)$ are the world lines of the particles and $\dot{z}^\mu_a = dz^\mu_a/d\tau_a$, m_a are their masses, and κ_5 is the five-dimensional gravitational constant. We assume that the brane lies in the $x^4=0$ hypersurface.

The effective energy-momentum tensor of the gravitational field, by analogy with the four-dimensional theory,[36] is given by

$$t^{\rm rad}_{MN}(x) = \frac{1}{4\kappa_5}\left\langle \partial_M \bar{h}^{\rm TT}_{ij} \partial_N \bar{h}^{\rm TT}_{ij} \right\rangle, \quad i,j = \overline{1,4}, \tag{5}$$

where a periodic motion of the source is assumed, and bracket $\langle \ldots \rangle$ denotes averaging over the period. In Eq. (5), we use the metric deviations in the transverse-traceless gauge

$$h^{\rm TT}_{0M} = 0, \quad h^{\rm TT}_{ii} = 0, \quad \partial^j h^{\rm TT}_{ij} = 0, \tag{6}$$

in which gravitational waves have five independent polarisations. Namely, polarisations of the plane wave propagating along the x^3-coordinate are presented by the matrix

$$\bar{h}^{\rm TT}_{ij} = \begin{pmatrix} h_+ - \frac{1}{2}h_\circ & h_\times & 0 & h_{14} \\ h_\times & -h_+ - \frac{1}{2}h_\circ & 0 & h_{24} \\ 0 & 0 & 0 & 0 \\ h_{14} & h_{24} & 0 & h_\circ \end{pmatrix}, \tag{7}$$

where the "cross" and "plus" polarisations are the same as in the four-dimensional theory[35,36]

$$h_+ = \frac{1}{2}\left(h_{11} - h_{22}\right), \quad h_\times = h_{12}, \tag{8}$$

and $h_\circ$ is the "breathing" mode[7]

$$h_\circ = \frac{2}{3}h_{44} - \frac{1}{3}\left(h_{11} + h_{22}\right). \tag{9}$$

The brane-living observer would detect only three of them – the standard "plus" and "cross", and the "breathing" polarisation, corresponding to the uniform shrinking and stretching of the probe masses circle lying in the plane orthogonal to the wave propagation direction.[7] We find that the breathing polarisation is non-vanishing even when both the source and an observer live on the brane.

3. Point particles contribution

To calculate the point particles contribution into the gravitational radiation we use the Rohrlich-Teitelboim definition of radiation[37–39] (see also[40–43]) based on the Lorentz-invariant decomposition of the on-shell energy-momentum tensor of the retarded field in the far zone. The Lorentz-invariant distance from the particle trajectory $z^M(\tau)$,

$$\hat{\rho} \equiv \hat{v}^M \hat{X}_M, \quad \hat{\rho} \xrightarrow{r \gg |\mathbf{z}|} r \tag{10}$$

is equivalent to the spatial distance from the system to the observation point. Here, the following notations are used:

$$\hat{X}^M = x^M - z^M(\hat{\tau}) \equiv \hat{\rho}\hat{c}^M, \quad \hat{c}^M\hat{v}_M = 1, \quad \hat{c}^2 = 0, \tag{11}$$

$$\hat{v}^M = v^M(\hat{\tau}), \quad v^M = \frac{dz^M}{d\tau}, \tag{12}$$

and $\hat{\tau}$ is the retarded proper time defined as

$$\left(x^M - z^M(\hat{\tau})\right)^2 = \hat{X}^2 = 0, \; x^0 \geq z^0(\hat{\tau}). \tag{13}$$

Then, in D dimensions, the on-shell energy-momentum tensor can be expanded in the inverse powers of $\hat{\rho}$ as follows

$$T^{MN} = T^{MN}_{\text{Coul}} + T^{MN}_{\text{mix}} + T^{MN}_{\text{rad}} \tag{14}$$

$$T^{MN}_{\text{Coul}} \sim \frac{A^{MN}}{\hat{\rho}^{2D-4}}, \quad T^{MN}_{\text{mix}} \sim \frac{B^{MN}}{\hat{\rho}^{2D-5}} + \ldots + \frac{C^{MN}}{\hat{\rho}^{D-1}}, \quad T^{MN}_{\text{rad}} \sim \frac{D^{MN}}{\hat{\rho}^{D-2}}. \tag{15}$$

Here, the most short-range part T^{MN}_{Coul} is the energy-momentum tensor of the Coulomb part of the field; T^{MN}_{mix} is the mixed part, which is absent in $D = 3$ and consists of more that one term in $D > 4$. The remaining long-range part of the energy-momentum tensor T^{MN}_{rad} has the properties allowing one to associate it with the energy-momentum flux carried by the emitted part of the field. Indeed, it is separately conserved $\partial_M T^{MN}_{\text{rad}} = 0$; it is proportional to the direct product of two null vectors $T^{MN}_{\text{rad}} \sim \hat{c}^M\hat{c}^N$, corresponding to the propagation of the associated energy-momentum flux exactly with the speed of light $\hat{c}_M T^{MN}_{\text{rad}} = 0$. Finally, it falls down as $T^{MN}_{\text{rad}} \sim 1/r^{D-2}$ and gives positive definite energy-momentum flux through the distant sphere of the area $\sim r^{D-2}$.

These properties hold both in even and odd dimensions. However, due to the Huygens principle violation, in odd dimensions the emitted part of the energy-momentum tensor T^{MN}_{rad} depends on the entire history of the source's motion preceding the retarded time $\hat{\tau}$, while in even ones it is completely determined by the state of the source at this moment. Also, due to the form of the energy-momentum tensor (5), which is the bilinear expression of the field derivatives, one can define its emitted part, by analogy with that of the energy-momentum tensor

$$(\partial_M \bar{h}^{\text{TT}}_{ij})^{\text{rad}} \sim 1/\hat{\rho}^{D/2-1}. \tag{16}$$

Therefore, the radiated energy flux through the distant $(D-2)$-dimensional sphere of radius r is given as

$$W_D = \int T^{0i}_{\text{rad}}\, n^i\, r^{D-2}\, d\Omega_{D-2}, \tag{17}$$

where $d\Omega_{D-2}$ is the angular element, and $n^i = x^i/r$ is a unit spacelike vector in the observation direction.

Considering the gravitational radiation from the non-relativistic binary system we demonstrate that to find the non-relativistic approximation of the emitted part

of the gravitational field produced by point particles one have to introduce, besides the small particles velocities $|\mathbf{v}| \ll 1$, another small parameter

$$\mathbf{s}(\tau) = \frac{\mathbf{z}(\hat{\tau}) - \mathbf{z}(\tau)}{\hat{\tau} - \tau}, \quad \lim_{\tau \to \hat{\tau}} \mathbf{s}(\tau) = \hat{\mathbf{v}}, \quad |\mathbf{s}| \sim |\mathbf{v}|, \tag{18}$$

which is of order of particles velocities for any moment of proper time. Then, we find the point particles contribution into the gravitational radiation from the binary system as

$$(\partial_M \bar{h}^{\rm P}_{ij})^{\rm rad} = -\frac{\mu\kappa_5 \bar{c}_M}{2^{3/2}\pi^2 r^{3/2}} \int_{-\infty}^{\bar{\tau}} d\tau \frac{\dot{a}_i v_j + 2a_i a_j + v_i \dot{a}_j}{(\bar{\tau} - \tau)^{1/2}}, \quad \bar{c}_M = [-1, \mathbf{n}], \tag{19}$$

where $z^i = z_2^i - z_1^i$ is the relative coordinate of the system, $\mu = m_1 m_2/(m_1 + m_2)$ is its reduced mass, and $\bar{\tau} = t - r$ is the retarded proper time calculated up to the leading order. Note that the emitted part of the gravitational field (19) is proportional to the null vector $\bar{c}_M$ leading to the corresponding energy-momentum tensor (5) being proportional to the direct product of two null vectors, in accordance with the Rohrlich-Teitelboim approach, and depends on the history of the system's motion preceding the retarded time $\bar{\tau}$.

4. Scalar field contribution

The scalar field stresses contribution into the gravitational radiation is calculated by use of the DIRE approach to the post-Newtonian expansions.[44] It is based on the splitting of the spacetime into the near zone, whose size is of order of the characteristic wavelength of gravitational radiation $\mathcal{R} = \mathcal{S}/|\mathbf{v}| \sim \lambda_{\rm GW}$ ($\mathcal{S}$ is the characteristic size of the binary system), and the radiation zone being exterior to the near zone.

In our calculations we assume that the observation point is in the radiation zone, the retardation of the scalar field inside the near zone is negligible, and that the energy-momentum density of the scalar field is non-vanishing only in the near zone being large enough due to the slow motion of the particles. Then, we arrive at the scalar field contribution into the gravitational radiation in the form

$$(\partial_M \bar{h}^{\rm F}_{ij})^{\rm rad} = -\frac{\mu\kappa_5 \bar{c}_M}{2^{5/2}\pi^2 r^{3/2}} \int_{-\infty}^{\bar{\tau}} d\tau \, \frac{\ddot{a}_i z_j + 2\dot{a}_i v_j + 2a_i a_j + 2v_i \dot{a}_j + z_i \ddot{a}_j}{(\bar{\tau} - \tau)^{1/2}}. \tag{20}$$

As the point particles contribution (19), this expression is proportional to the null vector $\bar{c}_M$ and depends on the history of the particles motion.

Combining the point-like (19) and the non-local scalar field (20) contributions, we find the emitted part of the total gravitational field of the binary system:

$$(\partial_M \bar{h}^{\rm TT}_{ij})^{\rm rad} = -\frac{\kappa_5 \bar{c}_M}{2^{5/2}\pi^2 r^{3/2}} \int_{-\infty}^{\bar{\tau}} d\tau \, \frac{\overset{\cdots\cdot}{Q}{}^{\rm TT}_{ij}}{(\bar{\tau} - \tau)^{1/2}}, \quad Q_{ij} = \mu \left[z_i z_j - \frac{1}{4} \delta_{ij} z_k z_k \right]. \tag{21}$$

As in the four-dimensional theory,[36] it is determined by the transverse-traceless part of the quadrupole moment of the binary system but now depends on the history of motion.

Therefore, using the Eqs. (5) and (17) we obtain the five-dimensional analog of the quadrupole formula for the angular distribution of the gravitational radiation power

$$\frac{dW_5}{d\Omega_3} = \frac{\kappa_5}{128\pi^4}\left\langle \mathcal{A}_{ij}^{\mathrm{TT}}\mathcal{A}_{ij}^{\mathrm{TT}}\right\rangle, \quad \mathcal{A}_{ij}^{\mathrm{TT}} = \int_{-\infty}^{\bar{\tau}} d\tau\, \frac{\overset{\cdots\cdot}{Q}{}_{ij}^{\mathrm{TT}}}{(\bar{\tau}-\tau)^{1/2}}. \tag{22}$$

depending on the entire history of the binary system's motion preceding the retarded time $\bar{\tau}$. Recently, the analogous formula was obtained by use of the spectral decompositions of the retarded Green's functions,[45] which are insensitive to the dimensionality of the spacetime, and can be considered as a confirmation of our result.

5. Binary system on a circular orbit

As the simplest application of the obtained five-dimensional quadrupole formula, we consider the gravitational radiation from the non-relativistic binary system on the circular orbit. Integrating the angular distribution (22), we find the total gravitational radiation power of the system on the circular orbit

$$W_5^{\mathrm{circ}} = \frac{5}{9\pi}\kappa_5\mu^2 R_{\mathrm{s}}^4\omega_{\mathrm{s}}^7, \tag{23}$$

where R_{s} is the orbital radius of the system, and ω_{s} is its frequency of the orbital motion. Also, using the energy conservation law

$$\frac{dE_{\mathrm{tot}}}{dt} = -W_5^{\mathrm{circ}}, \tag{24}$$

where E_{tot} is the total mechanical energy of the point particles, we analyse the quasi-circular orbit shrinking of the binary system arriving at the evolution laws for the orbital frequency and radius

$$\omega_{\mathrm{s}}(t) = \left(\frac{9\pi}{55\kappa_5}\right)^{3/11}(\sqrt{\mu}g_1g_2)^{-2/11}\,(t_{\mathrm{coal}}-t)^{-3/11}, \tag{25}$$

$$R_{\mathrm{s}}(t) = R_0\left(\frac{t_{\mathrm{coal}}-t}{t_{\mathrm{coal}}-t_0}\right)^{2/11}, \tag{26}$$

where t_{coal} is the moment of time corresponding to the coalescence of the binary system $R_{\mathrm{s}} \to 0$, $\omega_{\mathrm{s}} \to \infty$, and $R_{\mathrm{s}}(t_0) = R_0$. Note that the obtained Eqs. (25) and (26) differ significantly from their four-dimensional analogs

$$\omega_{\mathrm{s}}^{\mathrm{4D}}(t) \sim (t_{\mathrm{coal}}-t)^{-3/8}, \quad R_{\mathrm{s}}^{\mathrm{4D}}(t) \sim (t_{\mathrm{coal}}-t)^{1/4}, \tag{27}$$

what could be expected, given the five-dimensional nature of gravity and infinite size of extra dimension in our model.

Developments in numerical relativity and gravitational wave observations

Nigel T. Bishop
Department of Mathematics (Pure and Applied), Rhodes University, Makhanda 6139, South Africa
E-mail: n.bishop@ru.ac.za
www.ru.ac.za

This paper provides a summary of the fourteen talks that were presented in the session GW4 on various aspects of numerical relativity and computation concerning gravitational waves.

Keywords: Numerical relativity, gravitational waves

1. Introduction

A total of fourteen talks were presented over two days, covering a number of different topics within numerical relativity and computation concerning gravitational waves (GWs). Since the authors of each talk are publishing their work in these Proceedings or elsewhere, the purpose of this article is not to present any of the technical details of the talks. Rather, this session summary is aimed at presenting an overview of, and background information about, the various topics covered. As such, it is intended to be accessible to those working on other aspects of general realativty and astrophysics.

2. Inclusion of null infinity

Numerical relativity simulations of events such as compact object mergers, are normally carried out in a finite region, and the GW emission is estimated from the geometry near the outer boundary. However, because of the nonlinear nature of the Einstein equations, GWs are unambiguously defined only at future null infinity. Now the Einstein equations have the property that they can be compactified in a radial null direction and remain regular, so there are numerical approaches that compute GWs at future null infinity. The method commonly utilized is known as characteristic extraction, in which geometric data near the outer boundary of a merger simulation is used to provide boundary data to a characteristic code, i.e. one in which the spacetime is foliated by outgoing null cones. An alternative approach uses hyperboloidal slicing, in which the spacetime slices are spacelike in the central region, and become asymptotically null in the far region; however, this approach is less developed and has not yet produced gravitational waveforms.

Giannakopoulos *et al.*[1,2] presented results concerning the well-posedness of the Einstein equations in characteristic coordinates. In partial differential equation (PDE) theory, well-posedness in the standard L_2 norm is characterized by a system that is strongly (or symmetric) hyperbolic. However, it was shown that the characteristic Einstein equations form a PDE system that is only weakly hyperbolic. Further, it was demonstrated, using numerical examples, that weak hyperbolicity can have the effect of reducing the order of convergence of a code from that expected from considerations of the truncation error.

Gautam *et al.*[3] discussed a dual foliation formulation on hyperboloidal slices. There has been much effort over many years to implement a successful hyperboloidal scheme, but there remain problems of instability and of the need to regularize quantities that can become unbounded at null infinity. The essential idea presented is that these problems can be resolved by making a nonlinear change of variables, and the approach has been tested and shown to work in the special case of spherical symmetry. The approach is currently being extended to the general case, and if successful, this would be a significant achievement.

3. Surrogate models

Surrogate models have become an essential tool in searches in detector data for GWs from binary black hole mergers. Numerical relativity provides the most accurate waveforms, but they are computationally expensive and can take over a month for a single waveform. Since the merger phase space has, in principle, up to 7 dimensions, it is not feasible to populate it with numerical relativity waveforms. A surrogate waveform can be regarded as a mapping from (a restricted part of) the merger phase space to give a waveform. The quality of the model depends on how the mapping function is parametrized, and then fixing the parameter values so as to be consistent with known numerical relativity waveforms.

Islam *et al.*[4] reported a surrogate model for waveforms produced when the orbit is eccentric rather than circular. Eccentricity has long been neglected in waveform calculations, because it is well known that the reaction to GW emission damps out eccentricity at a rate that is much faster than that of the inspiral. However, there are possible astrophysical scenarios which could lead to the orbit being eccentric near merger, and the identification of such an event would be significant in terms of the understanding of formation channels of binary black hole systems. The model reported is restricted, at this stage, to non-spinning equal-mass black hole binary systems.

4. Effect of matter on GW propagation

As GWs pass through matter, some energy will be transferred to the matter causing the GW to be attenuated, but in astrophysical scenarios this effect is so small that it has been completely negelcted. However, recent work has shown that matter

can affect GW propagation in other ways, i.e. as a phase shift or as an echo. The possibility of a GW echo is interesting because there are (controversial) reports that echoes have been observed in GW data, caused by the remnant being some form of exotic compact object (ECO).

Naidoo *et al.*[5] applied a model of a GW source inside a shell of matter to GW events for which there are claims of echo observations. It was shown that any echo could not have been produced by the effect of a matter shell, since if it were the shell would have to be so massive as to constitute a black hole. Thus, confirmation of an echo in GW data would provide evidence in favour of the ECO hypothesis. However, it was also shown that there are astrophysical events, such as a binary neutron star merger and especially a core collapse supernova, for which the echo and phase-shift effects would alter the GW signal sufficiently for the difference to be measurable.

5. Hadron-quark phase transition in a binary neutron star merger

During the merger of two neutron stars, the matter becomes denser than nuclear matter and with a temperature of order $10^{12}\,^{\circ}$K, and it is feasible that a phase transition from hadronic matter to quark matter may occur. Such a phase transition would change the effective equation of state, and therefore would affect the motion of the matter and thus the emitted GW signal.

Hanauske *et al.*[6] considers whether a hadron-quark phase transition could lead to an observational signature of the event in the GW signal.[7–10] Computational models for a number of possible post-merger scenarios are constructed, and results obtained for the GW signal in runs to about 20ms. The results show that an increase in the frequency of the post-merger GW signal would indicate the occurrence of a phase transition.

6. Alternative theories of gravity

General relativity is consistent with every observation and experiment to date. However, there are reasons for investigating alternative theories. General relativity is not consistent with quantum mechanics, so it needs to be modified in a way that would affect its properties at a very small scale. On the other hand, at the very large scale of cosmology, the issues of the unknown nature of dark matter and dark energy may be resolved by using an alternative theory. Clearly, any alternative theory would need to be consistent with observations including those by LIGO/Virgo, and that motivates the need to calculate GW emission from compact object coalescence in the theory.

Lim *et al.*[11] reported the construction of a numerical code for an effective field theory with a Lagrangian that is that of general relativity plus terms that are quadratic in the Ricci tensor. The resulting field equations involve up to 4^{th} order derivatives. The code uses the harmonic gauge, and is restricted to the case

of spherical symmetry. It has been tested with initital data that is Minkowski or Schwarzschild plus noise, and has been shown to be stable and convergent.

Khlopunov *et al.*[12] calculates the GW emission due to a system of two point masses on a 3-brane embedded in a 5-dimensional spacetime, using analytical methods. In the non-relativistic limit, a generalization of the quadrupole formula is obtained.

7. GW memory

The memory effect in GW theory is well-known. Consider a system of free particles, each particle being at rest relative to the others, in a region of spacetime that can be regarded as initially Minkowskian. Supose that the particles are now perturbed by GWs, and that afterwards the spacetime region is again Minkowskian. Then the particles will be at rest relative to each other, but in general the positions of the particles relative to each other will have changed.

Grant *et al.*[13,14] generalizes the memory concept to the case that the particles have initial relative velocity and acceleration (due to forces other than gravity), and obtains formulas in terms of the GWs and non-radiative quantities for the memory-like changes to these quantities. In the case of zero relative velocity and acceleration, the formulas reduce to what is already known.

8. Searches for intermediate mass black hole (IMBH) mergers in GW data

IMBHs are usually defined as being in the mass range $10^2 M_\odot \leq M \leq 10^5 M_\odot$. They are less massive than the supermassive black holes at galactic centres, and too massive to have been formed by stellar collapse, because the pair instability gap means that stellar collapse cannot produce a black hole in the mass range $50 M_\odot \lessapprox M \lessapprox 130 M_\odot$. The event GW190521 is estimated to have been caused by the merger of black holes with approximate masses $85 M_\odot$ and $66 M_\odot$ yielding a remnant with mass about $142 M_\odot$, providing conclusive evidence for the existence of IMBHs. This observation has motivated searches that focus on identifying IMBH events in LIGO/Virgo data.

PyCBC is a free and open software package used to search for GW events in detector data. Chandra *et al.*[15] reported a PyCBC-based search that is optimized to identify IMBH events. The search re-identified GW190521 with a much better false alarm rate than that of the original search.

Gayathri *et al.*[16] presented, on behalf of the LIGO, Virgo and KAGRA collaborations, the results of their searches for IMBH events in the observing period O3.

9. Searches for a GW signal of a spinning neutron star

An object spinning with frequency f, unless it is exactly axisymmetric, emits GWs at frequency $2f$. Pulsars are spinning neutron stars that emit regular radio pulses,

and thus have rotational frequencies that are accurately determined. However, searches for GW signals from a number of pulsars have not yielded any positive result, and have only been able to place upper bounds on the magnitude of such signals. It is well-known that glitches occur in the radio pulses, indicating that some form of deformation is occurring in the neutron star. Thus it can be expected that there are periods of time during which the neutron star would be emitting GWs, but when such periods occur and their duration is not known.

Fesik *et al.*[17,18] presented a method for localising a long-duration signal in GW data, that is, to estimate the start time and duration of the signal. The method applies when the signal duration is much longer than the wave period, so more than a few hours. This knowledge can then be used to improve the signal-to-noise ratio of the recovered signal.

10. Machine learning

In recent years, the use of machine learning has become more and more commonplace throughout science, and this certainly includes applications to GW calculations and GW data analysis. The key advantages of machine learning are that: (a) in many circumstances it has proven to be remarkably accurate; and (b) there are now a number of software packages available, so from a user perspective, implementation can be straightforward. A common application of machine learning is the construction of a function that maps an input vector $\mathbf{x}$ to an output vector $\mathbf{y}$, i.e $\mathbf{y} = \mathcal{F}(\mathbf{x})$. We need to know the expected output $\mathbf{z}_i$ in a number of cases, and then construct $\mathcal{F}$ by minimizing the error $||\mathbf{z}_i - \mathbf{y}_i||$; this process is called *training* the network, and the quality of the network is described by the magnitude of the error, particularly for data points that are not used in the training.

Mishra[19] applied machine learning to search for a coherent WaveBurst in GW detector data. The network is trained on calculated waveforms of binary black hole mergers; the complete waveform is not used, but rather certain statistics representing the waveform are calculated, and these are used for the training. The resulting network is reported to improve the detection of binary black hole merger events by between 15% and 25%.

Field *et al.*[20,21] use machine learning to determine orbital dynamics of binary black hole systems from GW measurements. The system is written in the form of a universal differential equation, $\dot{\mathbf{x}} = \mathcal{F}(\mathbf{x})$, where $\mathbf{x}$ is a vector with components representing various aspects of the system dynamics. Once a choice of $\mathcal{F}$ is made, $\mathbf{x}$ is determined and then the quadrupole formula is applied to find the emitted GWs. Given observed (or numerically calculated) GW data from a binary black hole system, the next step is network training, i.e. to find $\mathcal{F}$ by minimizing the mismatch between this data and that associated with the choice made for $\mathcal{F}$. It was found that this model makes quite accurate waveform predictions outside the time interval over which the model is trained.

Insights into the Galactic Center environment from VHE gamma-ray observations with ground-based facilities

C. Fruck*

Physics Department, Technical University Munich,
James-Franck-Str. 1, 85748, Garching, Germany
E-mail: cfruck@ph.tum.de
www.ph.tum.de

The dynamic center of our galaxy is known to host a source of TeV gamma rays since the very beginning of the 21st century and a link to the supermassive black hole at the Galactic Center has been speculated on ever since. But not only the point-like source, spatially coincident with SgrA*, can be observed from the ground using the Imaging Air Cherenkov Telescope technique, but also diffuse emission from the vicinity, spanning more than one degree along the Galactic plane and emitting a remarkably hard energy spectrum, reaching energies well beyond 10 TeV.

Recent observations by the H.E.S.S., MAGIC and VERITAS facilities have enabled detailed studies of the dynamics of high-energy particles in Galactic Center region that indicate a link between the diffuse component and central point-like gamma-ray source. These studies suggest the presence of a powerful cosmic-ray accelerator in close proximity to SgrA*. This could potentially even be one of the long-sought-after Galactic PeVatrons, needed in order to explain the cosmic-ray spectrum up to the the feature called 'knee' at around 10^{15} eV.

Keywords: Galactic Center, SMBH, VHE gamma-ray astronomy

1. Introduction

The Milky Way Galaxy falls into the category of bared spiral galaxies, with a moderate star forming rate within the spiral arms and a significantly lower star forming rate inside the bar and bulge, towards its dynamic center. The bar and bulge span 1.5 and 4.4 kpc in size, respectively, while the the galactic disk extends over more than 30 kpc. A much smaller region at the center of the Galactic bulge contains a much higher density of young stars when compared to the surrounding regions. Such a high star-formation rate can only be maintained by a high density of molecular gas in this region, which is referred to as the Central Molecular Zone (CMZ) of the Milky Way Galaxy. The high star formation rate inside the CMZ is also the reason for the high density of high energy astrophysical phenomena being observed in this area of the sky. Those include pulsar wind nebulae (PWN), supernova remnants (SNR)[1] and presumably also millisecond pulsars (MSP).[2] All those types of

*Now at: Deutsches Zentrum für Luft- und Raumfahrt, Institut für Physik der Atmosphäre, Oberpfaffenhofen, Germany

objects can potentially accelerate charged particles to TeV energies and beyond, which can in turn produce very high energy (VHE) gamma rays through secondary processes like Bremsstrahlung or inverse Compton scattering in case of electrons or deep inelastic scattering in case of protons.

Another potential source of VHE gamma rays is the strong accumulation of dark matter (DM) that is expected around the Galactic Center (GC).[3] Some models predict DM particles to interact or decay with gamma-rays in the final state. The high expected DM density at the GC, paired with its relative proximity makes it one of the prime observational targets for indirect DM searches.[4] Strong foregrounds from astrophysical sources on the other hand complicate the search.

At the very center of the Milky Way Galaxy's rotation, spanning less than a 0.1 pc in size, resides the so-called S-star cluster with numerous O and B-type stars, whose rapid movement can be traced over a time scale of years with high resolution observations in the infrared.[5] The velocity of these stars and the tight elliptical orbits around a common dynamical center allow to quantify the central mass concentration, $\approx 4.4 \cdot 10^6\,\mathrm{M}_\odot$, and to exclude nearly all other explanations, except for the presence of a super-massive black hole (SMBH) at the dynamic center of our galaxy.[5] This mass concentration is spatially consistent with the point-like radio source SgrA*,[6] thus probably caused by non-thermal emission from the vicinity of the black hole (BH). The gravitational radius of such a BH would be

$$r_\mathrm{G} = \frac{2\,G\,M}{c^2} = 1.3 \cdot 10^{12}\mathrm{cm} \approx 10\,\mu\,\mathrm{arcsec}\,, \tag{1}$$

which is within reach for the most ambitious very-long-baseline interferometry (VLBI) campaigns, such as the *Event Horizon Telescope* (EHT) that utilizes a global network of radio telescopes.[7]

SgrA* is also visible in X-ray,[8] adding further evidence for non-thermal processes being at work and the acceleration of charged particles to high energies. In radio, infrared, as well as in X-rays, SgrA* shows minute to day-scale variability, changing its brightness over several orders of magnitude.[9,10] These observations indicate that the site of emission of non-thermal radiation must be comparable to the size of the BH itself and thus likely located in close proximity to the event horizon. Also from X-ray observations, echos on the scale of tens of parsecs have been identified within the surrounding structures of dense gas. These are believed to stem from past very strong X-ray flares caused by SgrA*, now visible as echos that can be seen traveling through the surrounding environment over a time scale of several years.[11] Another hint for an episode in the more distant past of strongly increased intensity of acceleration of high energy charged particles at the Galactic Center are the giant bubble-like structures found in X-rays[12] and gamma rays,[13] extending far outside the galactic disk in both directions. These structures can not be directly linked to SgrA* with certainty, but could potentially be the result of increased accretion activity onto the GC black hole.

2. VHE Gamma-Ray Observations from the Ground

The very dense and active astrophysical environment within the CMZ and especially the link between the SMBH, the closest to Earth by a large margin) and non-thermal processes visible in radio and X-ray, make the GC a very interesting target for observations in gamma rays. The *Fermi* large area telescope (LAT) in low earth orbit since 2008 is the most sensitive all-sky detector for gamma-rays in the energy range between 100 MeV and about 1 TeV.[14] While the GC hosts strong sources found also in the the *Fermi* source catalog, including a point source coincident with SgrA*,[15] the spatial resolution in the energy range around 10 GeV below is rather poor, while the effective collection area needed to cope with the low flux above that energy, is way large than the only about 1 m^2 offered by *Fermi*.

This is where ground-based facilities come into play, that in fact predate *Fermi* by more than a decade. The most successful class of ground-based instruments for observations in the very high energy (VHE) range between about 50 GeV and 100 TeV are so-called imaging air Cherenkov telescopes (IACTs). IACTs detect short ($\approx$ 3 ns long) and faint (hundred to a couple of ten thousand photons collected by the telescope) flashes of Cherenkov light produced in extensive air showers produced by gamma-rays interacting with the atmosphere generating charged leptons. These Cherenkov light flashes, mostly generated in the lower stratosphere and high troposphere, illuminate an area of several ten thousand m^2 on the ground at sea level. The light is collected by optical telescopes with simple geometry but large mirror area and fast as well as sensitive cameras, capable of time resolution on the order of nanoseconds. The reconstruction of the original direction of the VHE photons is strongly helped by employing stereoscopy and observing the same event with two or more telescopes placed within the light pool. The technique was pioneered by the Whipple[16] and HEGRA[17] instruments, but became a more established branch of astronomy with the next generation of telescopes. The three most important of those installations are the H.E.S.S.,[18] MAGIC[19] and VERITAS[20] experiments, located in Namibia, La Palma and the US, respectively.

The first detection of the GC in VHE gamma rays was already made with Whipple in 2004,[21] quickly followed up by detections with H.E.S.S. (2004)[22] and MAGIC (2006).[23] Later deep observations by H.E.S.S. have reveled further details of the GC VHE emission. In 2006, after subtracting the point sources at SgrA* and G0.9+0.1, the presence of diffuse emission throughout the CMZ has been reveled, spanning about 200 pc in width along the Galactic plane. The emission has been attributed to high energy protons interacting with the dense molecular clouds in the region.[24] The position estimate of the Galactic Center point source could be greatly refined, far below the gamma-ray PSF of the instrument. This lead to the exclusion of the SNR SgrA East as other potential source apart from SgrA*.[25] The spectral shape of the GC point source has been measured with high precision, yielding an index of around 2.2 and an exponential cut off at $\approx$ 10 TeV.[26]

3. Recent Observational Results

The recent increased interest that the GC received in VHE gamma rays has been sparked by the discovery of a gas cloud in 2011, on a highly eccentric orbit towards SgrA* in infrared, that led to speculations about a potential increase in accretion rate and possibly also flaring activity of the non-thermal emission of the object.[27] The pericenter passage was predicted to happen in 2013/14 with possible effects on the accretion rate around the time or later.[28] These revelations lead to a multi-year observation campaign by MAGIC, starting in 2012 and leading to a publication of the results covering the first four years of monitoring the gamma-ray source.[29] No variability of the GC point source has been detected until 2015, neither at energies above 1 TeV, nor at higher energies above 10 TeV, where some hadronic emission models predict a much faster reaction of the gamma-ray flux to newly injected particles compared to lower energy gamma rays.[30]

In 2016 the H.E.S.S. collaboration probed the extended emission from the Galactic Ridge in great detail, reveling that in contrast to the spectrum of the point-source, the gamma-ray spectrum emitted by this region reaches more than 30 TeV in energy without a hint for a cut-off.[31] Assuming proton-proton interactions as source for the emission, proton energies would thus not cut off before reaching around 1 PeV in energy. Another important finding from those observations is that the flux density of protons required to explain the observed gamma-ray emission profile, under the assumption of a density profile of molecular gas from CO emissions, best fits a $1/r$ shape, where r is the distance from the location of SgrA*.[31] Such an observation is compatible with cosmic rays (CRs) being accelerated in the vicinity of SgrA* and undergoing diffusion processes on their path away from the source. Combining both of those observations provides evidence that the GC might indeed host a Galactic PeVatron, potentially even linked to the SMBH SgrA*.

These findings were largely confirmed in 2020 by a new analysis of a large set of MAGIC data collected around the GC and CMZ. A new data analysis tool (SkyPrism[32]) for extended sources that allows fitting of 2D spatial models to gamma-ray sky maps binned in energy, similar to what is done by the *Fermi* tools,[33] was utilized for this analysis. This way individual energy spectra for 3 point-like (SgrA*, the PWN G0.9+01 and a recently discovered source inside the Galactic Radio Arc) and one extended source (the diffuse Galactic Ridge emission) could be extracted.[34] The energy spectrum of the diffuse component, in contrast to earlier findings by H.E.S.S., in this case shows a 2σ hint for a cut-off at around 20 TeV. It should however be noted that the regions probed and the methods used differ for both results. While the H.E.S.S. analysis extracted events from a cut anulus with inner radius of 0.1 and outer radius of 0.4 degrees around SgrA* and excluding the Arc source ("pacman" region),[31] the MAGIC analysis used a CS radio map that extends about 1.4 degrees and 0.8 along the Galactic plane as spatial template for this emission component.[34] Earlier in 2018 in second H.E.S.S publication concerning

the gamma-ray emission from the CMZ, a similar extraction region has been used for the spectrum of the diffuse component, showing a spectral shape compatible to the one found with MAGIC, exhibiting a similar downward trend above 10 TeV but not further commenting on it. Also the roughly $1/r$ spatial profile of the underlying proton flux density has been confirmed by MAGIC,[34] tending to somewhat higher values of α (≈ 1.2), especially when assuming an underlying constant CR-sea component in addition to the $1/r^{\alpha}$ profile.

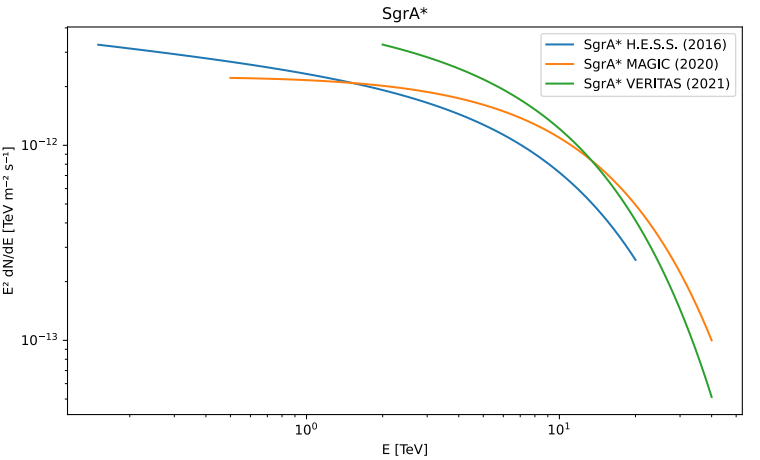

Fig. 1. Best fit SEDs of the point source coincident with SgrA* measured with H.E.S.S.,[31] MAGIC[34] and VERITAS.[35]

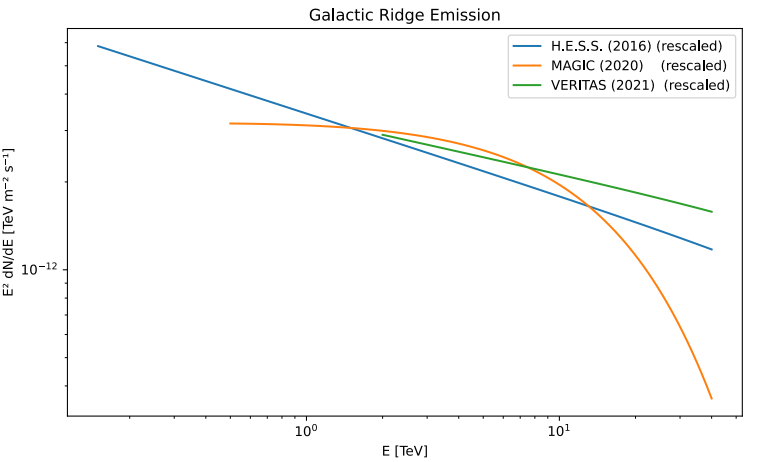

Fig. 2. Best fit SEDs of the Galactic Ridge emission measured with H.E.S.S.,[1] MAGIC[34] and VERITAS.[35]

The latest results of the current VERITAS GC observation campaign have been published in 2021, showing a nearly 10 y light curve of SgrA*, without a hint for variability, neither at energies above 2 TeV, nor above 5 TeV.[35] This study also presented an energy spectrum of the diffuse emission from the CMZ, extracted from Circular regions along the Galactic plane, but avoiding close proximity to SgrA*. Despite the complementary nature compared to the "pacman" region probed by H.E.S.S. (2016)[31] and the overlap with H.E.S.S. (2018)[1] and MAGIC (2020),[34] here no hint for a cut-off has been detected, with the spectrum continuing with an index around -2.2 until 30 TeV.

The best-fit spectral energy distributions (SEDs) from recent observations of the Galactic Center region[1,31,34,35] are illustrated in Figures 1 (spectrum of SgrA*) and 2 (Galactic Ridge). The SEDs measured for the Galactic Ridge have been slightly re-scaled in flux for better comparison, as not all correspond to the exact same extraction region. The Galactic Ridge spectra measured with H.E.S.S. and VERITAS have been fitted with a power law, while the MAGIC spectrum corresponds to a power law with exponential cut-off.

4. Conclusions and Outlook

The VERITAS result[35] highlights once more that the debate about the nature of the GC gamma-ray source and and CR accelerator is still open and further observations are necessary in order to gain even better insight to the underlying physics. It is unclear weather the current generation of Cherenkov telescopes are sufficient for the task at hand, or if new discoveries will mainly rely on the next generation of IACTs, the telescopes of the Cherenkov Telescope Array (CTA) currently under construction.[36] Also instruments utilizing the water Cherenkov technique like the recently commissioned HAWC[37] and LHAASO[38] could play an important role in the future. While on one hand lacking the angular resolution, those instruments do not suffer from the limited field of view of IACTs and can accumulate vast amounts of data with relatively low irreducible background. This makes them perfectly suited for putting the GC and CMZ into context with the larger scale emission from the rest of the Galactic plane. Being located on the northern hemisphere, HAWC and LHAASO themselves are not ideally suited for the task, but the upcoming Southern Wide-Field Gamma-Ray Observatory (SWGO) might well be.[39]

The Tunka Advanced Instrument for Gamma-ray and cosmic ray Astrophysics (TAIGA) is a hybrid experiment for the measurement of Extensive Air Showers (EAS) with good spectral resolution in the TeV to PeV energy range. In this domain, the long-sought Pevatrons can be detected. Currently the hybrid TAIGA detector combines two wide angle shower front Cherenkov light sampling timing arrays (HiSCORE and Tunka-133), two 4m class, 10° aperture Imaging Air Cherenkov Telescopes (IACTs) and 240 m^2 surface and underground charged particle detector stations. Our goal is to introduce a new hybrid reconstruction technique, combining the good angular and shower core resolution of HiSCORE with the gamma-hadron separation power of imaging telescopes. This approach allows to maximize the effective area and simultaneously to reach a good gamma-hadron separation at low energies (few TeV). At higher energies, muon detectors are planned to enhance gamma-hadron separation. During the commissioning phase of the first and second IACT, several sources were observed. First detections of known sources with the first telescope show the functionality of the TAIGA IACTs. Here, the status of the TAIGA experiment will be presented, along with first results from the current configuration.

Keywords: Gamma-rays: experiments; Observations: Crab Nebula.

1. Introduction

TAIGA stands for Tunka Advanced Instrument for Gamma-ray and cosmic ray Astrophysics, and is a hybrid instrument designed to access the gamma-ray energy range from approx. 1 TeV to several 100s of TeV. The experiment is located at an altitude of 675m above sea level on the site of the Tunka-133[1] cosmic ray array (51°48'35"N, 103°04'02"E). Observations in this energy range are motivated by several questions of Astroparticle and particle physics. The presence of cosmic ray (CR) accelerators within our Galaxy can be inferred from observations of diffuse and extended gamma-ray emission in the High-Energy (HE)[2] and Very-High-Energy (VHE) range[3–5] e.g. These Gamma-ray emissions result from the decay of neutral

pions, which are produced in interactions of the accelerated cosmic rays with the ambient interstellar medium, i.e. molecular gas clouds, which effectively act as CR tracers.[6] The gamma-ray energy range from 10 TeV to few 100 TeV is crucial for the search for the Galactic Pevatrons, which accelerate cosmic ray particles up to knee-energies (approx. 3 PeV proton energy). Due to the typical inelasticity of hadronic interactions, the cutoff energy of Pevatrons in the gamma-ray regime is located at energies of several 100 TeV. Hard gamma-ray spectra in this energy range are much less ambiguously attributable to the hadronic rather than leptonic emission mechanism, because the cross-section for inverse Compton scattering drops with increasing energy (Klein-Nishina regime). Recent neutrino observations[7] and the detection of gamma-rays at ultra high energies by LHAASO[8] emphasize the potential of the search for the Galactic Pevatrons. The detection of Pevatrons, and their spectroscopic, and morphological resolution in their cutoff energy regime are the main physics goals of TAIGA.

Beyond 10^{17} eV, the origin of CR is assumed to be extra-Galactic (EG). Due to the development of intergalactic pair cascades, the accelerators of EG cosmic rays (EGCR) might exhibit a halo-like gamma-ray emission. Furthermore, one can expect an enhancement of EGCR from the local galactic supercluster.[9] The intergalactic pair cascades from that direction could create an anisotropic gamma-ray emission, observable with a wide field of view.

In the energy range of 100 TeV to several PeV, absorption due to pair creation becomes relevant also for Galactic sources. The attenuation of Galactic gamma-ray signals via production of e^+e^--pairs reaches a maximum around 100 TeV from the Galactic interstellar radiation field (IRF) and at 2 PeV from the cosmic microwave background (CMB).[10] This opens up the possibility to measure the density of the IRF, provided the distance of the emitting object is known. At PeV energies, the relevant field is the CMB, which is universal and very well known. Therefore, a possibility might exist to measure distances from a CMB absorption feature, i.e. cutoff in energy spectra of the most energetic Galactic gamma-ray sources. Another variable comes into play when considering the possibility of photon/axion conversion[11] or photon/hidden-photon oscillations,[12] because axions and hidden-photons could propagate without interaction, reconvert to photons, thus reducing the attenuation effect by pair production. Another fundamental effect on the attenuation by pair production might be the modification of the e^+e^- pair production threshold due to Lorentz Invariance violation. In a more direct way, other, non-thermal, dark matter candidates (e.g. wimpzillas) with masses ranging from 10^{12} GeV to 10^{16} GeV can be searched for in the energy range considered.

Furthermore, the chemical composition of Cosmic rays can be measured with TAIGA in the transition range from a Galactic to extragalactic origin ($\approx 10^{15}$ eV to 10^{17} eV) and in the energy range above, where the composition of cosmic rays is still poorly understood.[13] Furthermore, TAIGA will allow measurements of cosmic ray anisotropies beyond 100 TeV primary energy. Finally, observations of EAS can

also address fundamental questions of particle physics such as measurements of the proton-proton cross-section, or the search for quark-gluon plasma.

2. The TAIGA Experiment

In the TAIGA experiment, a hybrid approach using different detection techniques is used. While both Cherenkov photon and particle identification are used, the term hybrid also, and foremostly, refers to the hybrid Cherenkov technique. The angle-integrating air shower timing array TAIGA-HiSCORE is combined with the imaging air Cherenkov Telescopes TAIGA-IACT. The timing array is a cost effective method for the instrumentation of very large detector areas, and it provides good angular, core position, and energy resolution in the energy range above few 10s of TeV. The IACTs provide the air shower image shape for good gamma-hadron separation. When used in stand alone mode (i.e. no stereo), one IACT can detect air showers at a distance of 300 m - and more - from the shower core. Both detector components together provide the most relevant key parameters: direction and core from HiSCORE-TAIGA and image shape (width, length) from IACT-TAIGA. Placed at a distance of about 600 m from each other, 4 IACTs can cover a HiSCORE array of more than 1 km^2 area. It has been shown that using such a hybrid approach with only few IACTs per km^2, combined with a HiSCORE array, achieves a competitive gamma-hadron separation in the energy range above 10 TeV.[14] At energies higher than 100 TeV, the measurement of the muon component of the EAS using particle detectors on the surface and underground will enhance the gamma-hadron separation further.

Currently, TAIGA consists of a total of 120 HiSCORE stations deployed on an area of 1 km^2, and two 4 m class imaging air Cherenkov telescopes (IACTs) with a 10° aperture. A third IACT is planned for 2022. The distance between the IACTs was chosen as 300 m in the prototype phase of TAIGA. In future, distances of up to 600 m are planned. Additionally, scintillator stations for charged particle detection with a total surface of 240 m^2 are deployed above and below ground for the measurement of the muon component of EAS. The layout of the TAIGA-HiSCORE and TAIGA-IACT components is shown in Figure 1. The current TAIGA pilot array is used for a proof of principle of the detector concept. In future, an optimized array layout will take advantage of the hybrid method, that allows larger separations between the individual IACTs.

2.1. *TAIGA-HiSCORE*

HiSCORE is an array of angle-integrating air Cherenkov detector stations, distributed over an area of approximately 1 km^2. As shown in Figure 1, the stations are arranged in rows offset to each other with inter-station distances of 75 m to 150 m. Each station consists of 4 8 inch (and 10 inch) photomultiplier tubes (PMTs, ElectronTubes and Hamamatsu) with a segmented Winston cone (Alanod 4300UP foil), resulting in a light sensitive area of 0.5 m^2 per station. The viewing cone of

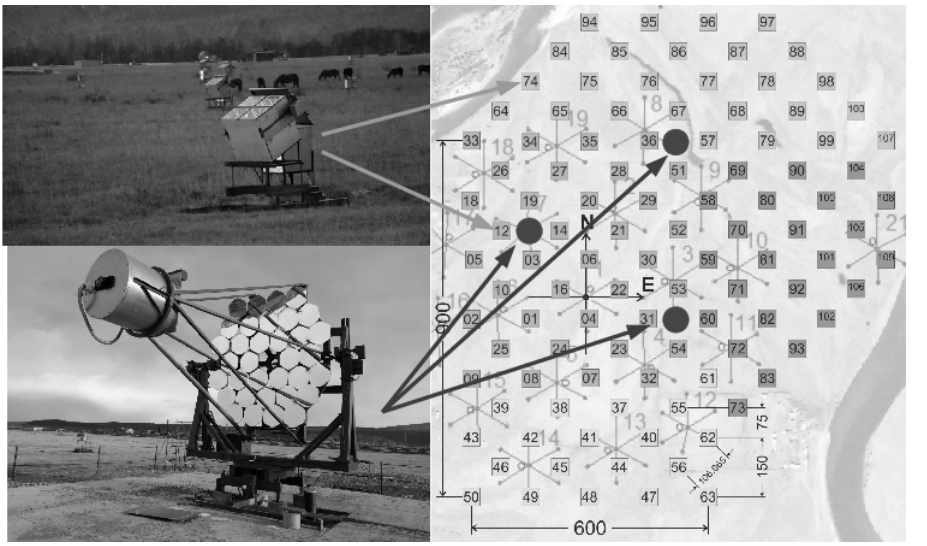

Fig. 1. Layout of the TAIGA-HiSCORE array. Only the HiSCORE and IACT components are shown. The first two IACTs were deployed from 2016 to 2019. The third IACT will be deployed until 2022. The HiSCORE array currently consists of 89 stations and will be extended to 120 stations by the end of 2021.

one station has a diameter of 60°, resulting in an effective field of view of 0.6 sr. An analog summator sums up the signals of all four channels. The sum is used for triggering, and the individual channels are read out with a DRS 4-based 9-channel readout board at a sampling rate of 2 GHz. Four anode signals and four dynode signals (low gain channel) are read out. Channel number 9 is used for time synchronization, based on the sampling of a 100 MHz clock signal. This custom time-synchronization was cross checked with the WhiteRabbit system. It could be verified that the time synchronization works on a level of 0.2 ns relative timing accuracy.[15,16] Each detector station is connected to the central DAQ via optical fibre. The signal traces are processed to extract the amplitude and the timing (half-rise-time, full width half maximum). Based on these parameters, the air shower arrival direction, core impact position, and energy are reconstructed using the methods developed for Tunka-133 and HiSCORE.[1,16,17] Monte Carlo simulations were used to evaluate the detector performance, resulting in resolutions for core position (O(15 m)), energy (20%), and direction (0.1°). Moreover, the serendipituous discovery of a pulsed signal from the CATS lidar onboard the international space station allowed to verify the absolute pointing of the experiment.

2.2. *TAIGA-IACT*

Currently, two IACTs are in operation on the TAIGA site. A third IACT is under construction. The TAIGA IACTs are based on a Davies-Cotton design, with

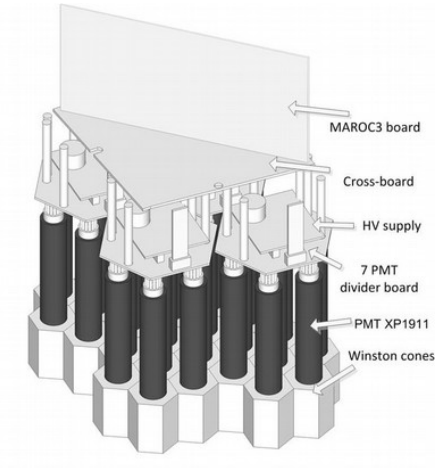

Fig. 2. Layout of a camera cluster of 28 PMTs. The high voltage is supplied to subgroups of 7 pixels. Each cluster is equipped with a MAROC-3 ASIC board.

a tesselated mirror dish of 34 facets with 60 cm diameter each, resulting in a mirror area of about 10 m^2. Each axis of the alt-az dish mount mechanics is driven by a stepper motor equipped with shaft-encoders for pointing positioning. Additionally, a sky-CCD system is used for pointing calibration. A verification of the absolute pointing accuracy of 0.02°, was carried out by the measurement of the anode current in the central camera PMT-pixel in a drift-scan accross a known bright star position.[18] The PMT camera of IACT-1 consists of 560 XP1911 PMTs (diameter 19mm). The second IACT is equipped with 595 PMTs. Both cameras have a field of view of 9.6° and are placed at the focal point at 4.75 m distance from the respective dishes. For enhanced light collection, and noise suppression from stray light, a Winston Cone plate is attached to the PMT camera plane. The PMTs are organized in clusters of 28 pixels (see Figure 2). All channels are read out with a 64 channel ASIC MAROC-3 board. The board provides a fast shaper which is used for triggering and a slow shaper which is used for read out. The camera electronics for the first two TAIGA-IACT cameras are described elsewhere.[19,20]

Air shower event images, such as shown in Figure 3, are reconstructed using the pixel amplitude distributions in the camera, either based on classical moment analysis,[21] or more advanced machine learning algorithms.[22]

2.3. *TAIGA Muon array*

The TAIGA-Muon array[23] consists of scintillation counters on a total area of currently 240 m^2. The muon detector stations are distributed above and below ground. In a future stage, a 5 times larger instrumented area is planned. Each TAIGA muon detector consists of four triangular sectors of scintillator material. The sectors are connected with wavelength shifting bars that guide the light to small PMTs (FEU-85). Measurements of cosmic rays have yielded an average cosmic ray muon amplitude of 31p.e.±20%. The TAIGA-Muon array develops its power

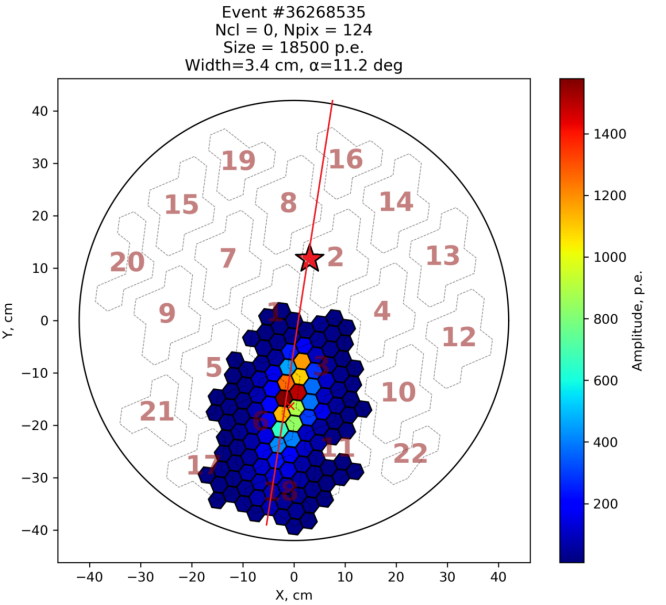

Fig. 3. Real data event for IACT1. The numbered shapes correspond to the above described clusters. The star shows the direction of the air shower event as reconstructed by the HiSCORE array. The total amplitude summed over pixels (size) is 18500 photoelectrons (p.e.). The alpha angle of the major axis is 11.2 degrees, and the measured image with (second image moment) is 0.41 degrees.

at higher energies, starting at about 100 TeV, where the measurement of the muon component of EAS helps in discriminating hadrons from gamma-rays, as well as identifying the nature of the hadronic cosmic rays.

2.4. *Hybrid technique*

A large instrumented detector area is key for accessing very high energies from few TeV to several 100s of TeV. Using only IACTs and the well-established stereoscopic technique requires a large number of channels per instrumented km^2, because firstly, each IACT has a large number of camera channels, and secondly, the IACTs cannot be placed too far away from each other, in order to detect the same EAS in at least two IACTs for stereoscopic reconstruction. As opposed to that, the instrumentation of large areas with a timing array such as HiSCORE is more cost effective, requiring considerably lower number of channels per km^2. However, while gamma-hadron separation is possible with HiSCORE alone to a certain degree (and improving with increasing energy[17]), the separation power stays below the quality reached with IACTs. Therefore, TAIGA implements a novel hybrid technique, taking advantage of the strengths of both Cherenkov techniques. The effective area is maximized using the timing array principle, and the gamma-hadron separation is optimized using

the IACTs. More specifically, the strong points of HiSCORE are the directional and core position resolution. The strength of the IACTs is the image shape. The IACTs can be placed so far apart from each other, that each IACT is operated in monoscopic mode, meaning that the Cherenkov lightpool of one air shower event only hits one IACT, as shown in Figure 4. Without requiring a stereoscopic trigger, the effective area of each IACT can be fully exploited and only 4 IACTs are needed in order to cover an area of the order of $1\,\mathrm{km}^2$. The loss of reconstruction quality when using the IACTs in monoscopic mode as compared to stereoscopic mode can be recuperated using the information of the HiSCORE array on angular and core position, as illustrated in Figure 5. The major axis of the IACT image in that Figure is pointing towards the core position, which cannot be reconstructed with the IACT alone, but is provided by the HiSCORE array. For comparison, a classical method for hadron suppression in stereoscopic systems is to use the mean scaled width parameter, for which the core position is reconstructed stereoscopically and the image widths of all IACTs are scaled according to MC-expectation. A similar parameter in TAIGA is the hybrid scaled width, which is the image width from one IACT, scaled with the MC-expectation for the given image size and using the core position and direction as reconstructed by HiSCORE. It was shown that the hybrid scaled width achieves competitive rejection power.[14] As opposed to stereoscopic systems, this method does not suffer from deteriorating core impact resolution at large distances (over the full HiSCORE array, the core resolution is the same) and also does not require closely spaced IACTs. The sensitivity of the air Cherenkov components of the TAIGA experiment was estimated using MC-simulations and is shown in Figure 6.

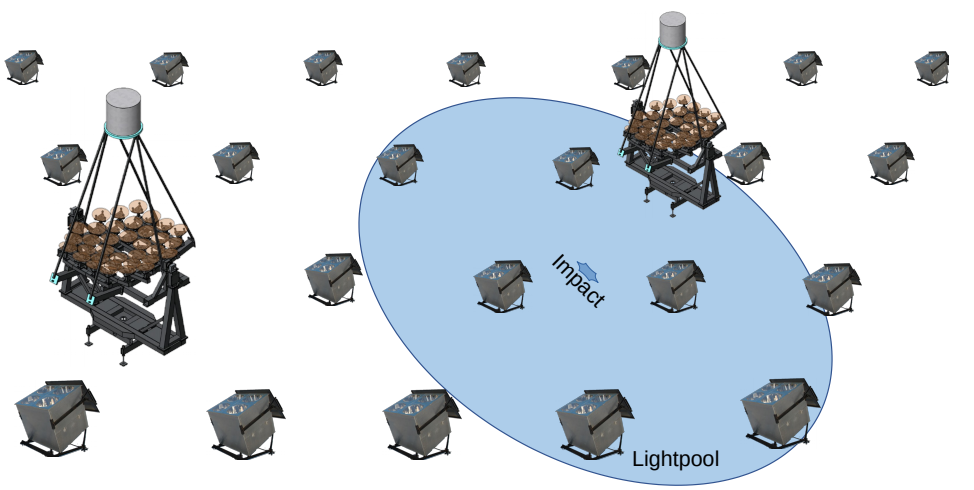

Fig. 4. Schematical drawing of the principle of hybrid operation.

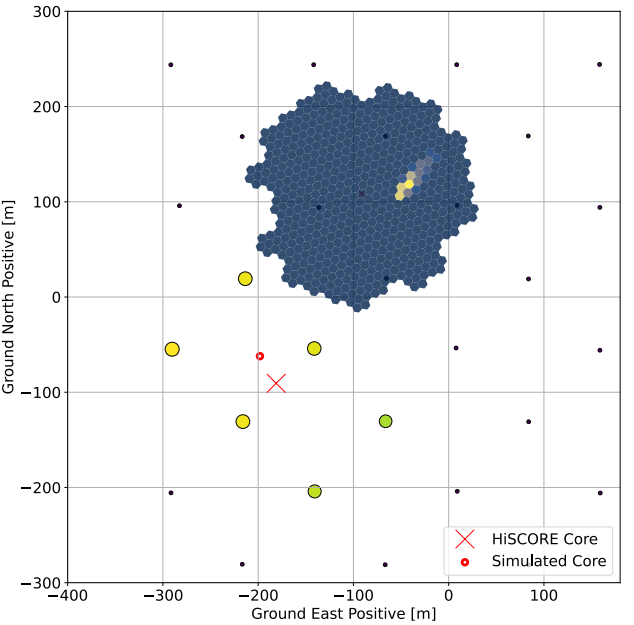

Fig. 5. Simulated hybrid event: as explained in Figure 4, the EAS impact position is reconstructed using the HiSCORE array. The major IACT image axis projected to the ground reference frame (not drawn) is pointing towards the position of the reconstructed core impact position.

3. First results

3.1. *TAIGA-HiSCORE*

The angle integrating HiSCORE array was installed in several stages since 2016. The performance of the array was estimated using from MC-simulations and real data. The relative angular and core position resolutions using a subdivision of the array into subarrays (chessboard method) could be reproduced in simulations, verifying the expected performance of TAIGA-HiSCORE.[24] The relative station timing is calibrated using stationary light sources and air shower data. A fast moving source in the field of view of the array turned out to be the CATS Lidar onboard the international space station. This light source could be used to verify time synchronization and absolute array pointing.[15,16] As compared to the Tunka-133 array, the measurement of the cosmic ray energy spectrum could be extended to lower energies with TAIGA-HiSCORE, as indicated in Figure 7.

3.2. *TAIGA-IACT*

The MC detector simulation for the TAIGA-IACTs is done using two simulation chains: a custom MC simulation chain, and an adaptation of the *sim_telarray* package.[25] The image pixel photoelectron scale is calibrated using an LED illuminating

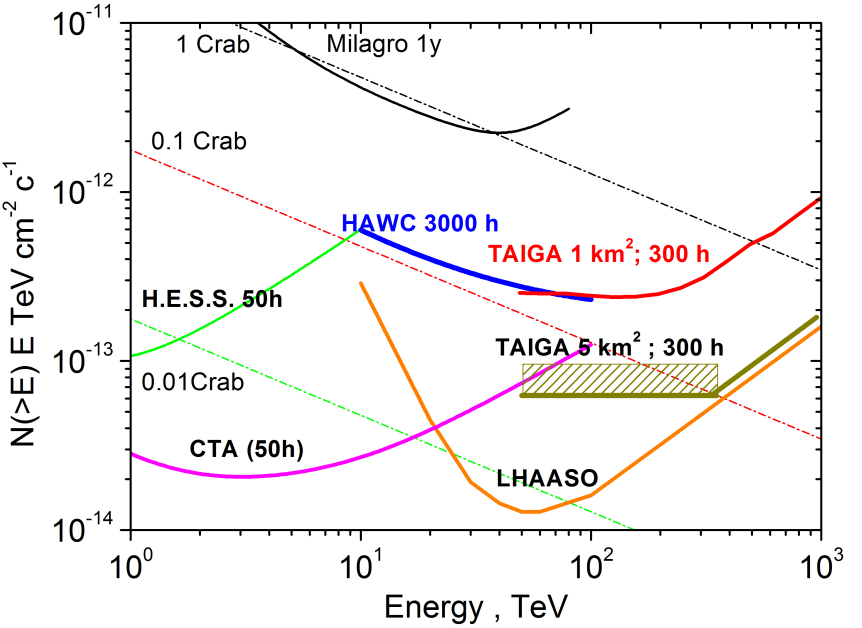

Fig. 6. Sensitivity of the TAIGA experiment for 300 hours of observations in hybrid mode (without muon detectors). A comparison to sensitivities of other experiments is not straight forward, since also the angular and spectroscopic resolutions play an important role for measurements of the morphology and spectra of astrophysical objects. TAIGA has a relative energy resolution of better than 20% and an angular resolution of the order of 0.1°.

the whole PMT camera. Raw data are processed using two independent reconstruction chains to obtain air shower images (amplitude distributions of all pixels for each event). Four different high-level analyses, based on the robust Hillas-parameters, were applied to these image data. Figure 8 shows a comparison of the amplitude distributions of the second-hottest pixel in real data and simulation. A comparison of simulated and real image width is shown in Figure 9. The simulations describe real data reasonably well.

After commissioning of the first TAIGA-IACT, our primary goal was to demonstrate that the IACT is operational. For this purpose, observations of the standard candle, the Crab Nebula, were carried out. After weather quality selection, a total data set of 40.5 h is obtained for analysis. Observations were taken in the wobble mode (Wobble offset 1.2deg). The position of the Crab Nebula inside the IACT camera is taken as the on-source region and the background was estimated from off-source regions at identical distances to the camera center, from the same dataset. The distribution of the alpha angle between the major image axis and the position of the Crab Nebula inside the camera is shown in Figure 10. Selecting events with an image size of at least 120 p.e., a clear excess can be observed. With a zenith angle of 31deg, and taking into accout the altitude of the observation level, the efficiency

of the optical system, and the cuts applied, the energy threshold of this data set is 4.5 TeV . The significance[26] of the observed excess is $6.3\,\sigma$ (using a cut on alpha smaller than 10deg).

4. Conclusion

The novel hybrid technique of the TAIGA pilot array combines the angle integrating air Cherenkov timing techinque with 4 m class imaging air Cherenkov telescopes, taking advantage of the strengths of both techniques, i.e. large instrumented areas with the HiSCORE array, and gamma-hadron separation from image shape using the IACTs. Additionally, a scintillator detector for particle detection above and below ground will allow the measurement of the muon component, for improved gamma-hadron separation at higher energies. The expected sensitivity of the future $5\,\mathrm{km}^2$ stage is in the region of $10^{-13}\mathrm{photons\,cm^{-2}s^{-1}}$. First stages of the 3 TAIGA detector components are in operation. Monte Carlo simulations were compared to real data, showing a good understanding of the detecots. Observations of the Crab Nebula for 40.5 h above 4.5 TeV resulted in an excess of $6.3\,\sigma$.

Science perspectives of the Southern Wide-field Gamma-ray Observatory (SWGO)

K.L. Engel* for the SWGO Collaboration

Department of Physics, University of Maryland, College Park; 4150 Campus Dr, College Park, MD, USA 20742

**E-mail: klengel@umd.edu*

We outline the science case for SWGO, the Southern Wide-field Gamma-ray Observatory, an air-shower array planned for construction at a high-altitude site in the Southern Hemisphere. This next-generation, wide-field-of-view, gamma-ray survey instrument will be sensitive to gamma rays from $\sim$ 100 GeV to beyond 100 TeV energies and, due to its location and features, will be complementary to other gamma-ray observatories such as HAWC, LHAASO, and CTA. SWGO's scientific endeavors will cover a broad range of exciting topics, such as monitoring the transient sky at very high energies, unveiling Galactic and extragalactic particle accelerators, probing particle physics beyond the Standard Model, and the characterization of the cosmic ray flux. With its novel design, SWGO stands poised to provide the world's best sensitivity across many facets of our exciting field.

Keywords: Instrumentation: detectors; gamma rays: general

1. Introduction

With an abundance of "paradigm-shifting" discoveries in the field of high-energy particle astrophysics in the last decade, it is critical for the continued growth of these topics and movement into potential new discovery space that there be facilities in both hemispheres capable of continuously surveying the gamma-ray sky in the time and space domains. Ideally, such an instrument would have a very wide field of view, making it capable of providing transient alerts to the astrophysics community in addition to having an abundance of archival data for performing follow-ups from other notifications. It is also important that this new facility be ground-based, collecting information from extensive air showers, as necessitated by the declining flux emitted by cosmic sources at very-high energies. We believe that the Southern Wide-field Gamma-ray Observatory (SWGO), a water-Cherenkov facility to be located in the Southern Hemisphere, fills this pivotal role within the astrophysics and high-energy particle physics communities.

The complementarity between IACTs and a wide-field-of-view ground-based particle array such as that outlined herein is summarized by Table 1, from the Science Case White Paper for a wide-field-of-view gamma-ray observatory in the Southern Hemisphere.[1]

This work is intended to highlight endeavors presented in Ref. 1, as well as additional efforts since the time of that document's publication, and is the collective work of the whole of the SWGO Collaboration.

Table 1. Comparison of typical performance of current and planned IACT arrays and ground particle arrays for gamma-ray astronomy. See Ref. 1 for details.

	IACT Arrays	Ground-particle Arrays
Field-of-view	3°–10°	90°
Duty cycle	10%–30%	>95%
Energy range	30 GeV – >100 TeV	∼500 GeV – >100 TeV
Angular resolution	0.05°–0.02°	0.4°–0.1°
Energy resolution	∼7%	60%–20%
Background rejection	>95%	90%–99.8%

2. The Southern Wide-field Gamma-ray Observatory (SWGO) Concept

SWGO is a proposed future water Cherenkov experiment in the Southern Hemisphere for the ground-based detection of astrophysical gamma rays. The core unit will use the water-Cherenkov technique to observe intensive air showers from primary particles incident on the Earth's atmosphere and would be the most sensitive gamma-ray observatory in the Southern Hemisphere above 10 TeV, with expected sensitivity up to PeV energies. With an array of such detections, similar to the operational mode of the HAWC Observatory in the Northern Hemisphere,[2] the energy and direction of the incident gamma ray that produced the shower can be determined.

The exact design of SWGO is potentially dependent on site choice, with water access, construction costs, and infrastructure feasibility all playing deciding roles in addition to compatibility with science-driven main design goals. The aim of the design such a next-generation observatory, no matter the specifics, is to achieve roughly an order of magnitude higher sensitivity over the current-generation of instruments like HAWC.[1]

Being the most sensitive observatory in the Southern Hemisphere above ~ 20 TeV (as seen in Figure 1) would make SWGO an ideal complement not only to Northern Hemisphere observatories, but also to CTA South. It's complementarity with Northern Hemisphere observatories is well visualized by comparing SWGO's projected field of view with that of the HAWC Observatory, shown in Figure 2. By placing SWGO in the Southern Hemisphere, we would have a prime view to monitor sources and source regions previously inaccessible or mostly in accessible to HAWC, such as the Galactic Center and the Magellanic Clouds, as well as more ideal viewing of source regions such as the Fermi Bubbles.

3. The Core Science Case

The following list is just an overview of the science we intend to do with SWGO once built, with promising sensitivity studies currently being conducted on all fronts.

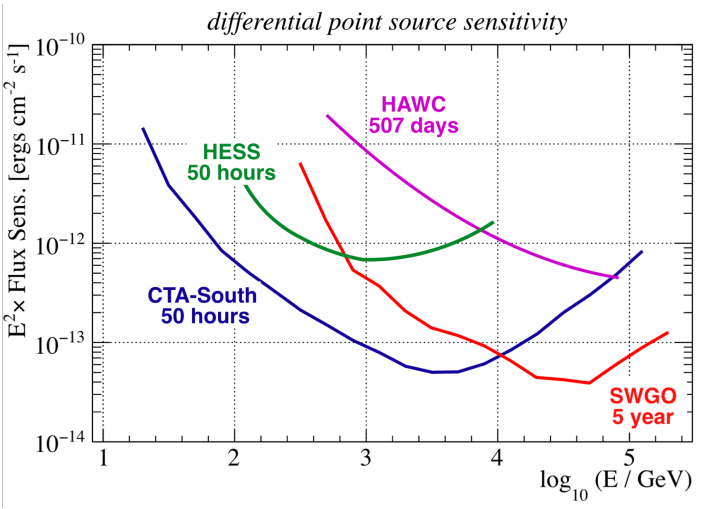

Fig. 1. The five-year differential point-source sensitivity of SWGO, anticipated to bbe the best in the Southern sky above tens of TeV. Figure from Ref. 3.

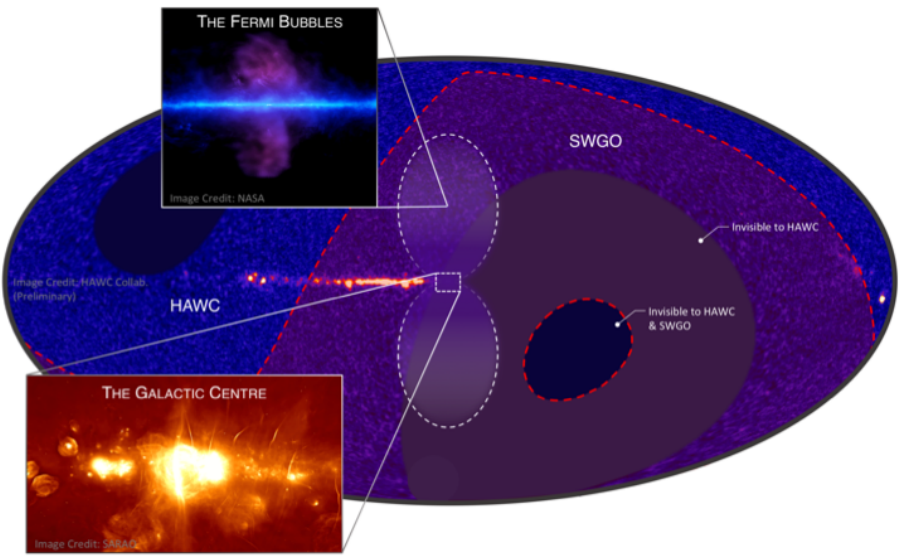

Fig. 2. Sky coverage of SWGO in Galactic coordinates (red dashed line) overlaid on the HAWC significance map containing over 50 sources. Figure from Ref. 3.

The core science cases of SWGO, as enumerated in Ref. 1, are:

- Detection of short-timescale phenomena[4]— low-energy threshold for detection of short-timescale (<1 hr) transient events down to 100 GeV

- Search for PeVatrons[5]— Improved sensitivity up to a few 100s of TeV to search for PeV Galactic particle accelerators
- Pulsar Wind Nebulae (PWNe) and Gamma-ray halos[6]— Unique potential for accessing the high-energy end of the Galactic population
- Dark matter and diffuse emission[7,8]— Unique access to the Galactic Center and Halo at the high-energy end of the spectrum
- Cosmic rays[9]— Unique complement to LHAASO for anisotropy studies, with the capability to reach low angular scale. Additionally, good muon tagging implies good mass resolution for composition studies up to the *knee*

3.1. *The High-Energy Transient Sky*

There are four key targets of interest in the high-energy transient sky—gravitational waves (GWs), fast radio bursts (FRBs), high-energy neutrinos, and gamma-ray bursts (GRBs)—to which the applied properties of SWGO will be a unique advantage for observing.

3.1.1. *Gravitational Waves*

GRB 170817A and the subsequent kilonova emission associated with binary-neutron-star (BNS) merger GW 170817 launched the field of GW multimessenger astronomy. SWGO's wide field of view and large, unbiased duty cycle would allow the recording of real-time, high-energy gamma-ray data for all GW events falling into its field of view. This would provide coverage of high-uncertainty regions, locate very-high-energy counterparts, and search for currently unmodeled burst-like GW signals. SWGO could even provide real-time notifications to other Southern Hemisphere telescopes and observatories, *e.g.,* CTA, so that they might perform detailed follow-up observations.

3.1.2. *Fast Radio Bursts*

Monitoring approaches by IACTs of FRBs are less than ideal as the duty cycle of FRBs is poorly constrained. A wide-field-of-view survey instrument like SWGO is therefore ideal for Galactic FRB follow-ups to provide constraints on gamma-ray emission in coincidence with bursts detected in the radio domain, as well as monitoring for repeaters. Simulation studies have also predicted that 60–70% of FRBs are located in the Southern Hemisphere, so SWGO's location will be incredibly advantageous for the study of these objects.

3.1.3. *High-Energy Neutrinos*

As evidence for the interaction of high-energy hadronic particles, high-energy neutrinos are crucial in the search for sources of high-energy cosmic-ray accelerators,

but a multimessenger approach is necessary to determine the source of the astrophysical flux of high-energy neutrinos. This multimessenger approach, towards which SWGO's large, unbiased duty cycle will be an invaluable tool, greatly aids neutrino studies as high-energy gamma-ray observations allow precise localization of the emission region, allowing for not only the identification of their astrophysical source, but also information about overall source energetics and energy- and time-dependent power output.

3.1.4. *Gamma-Ray Bursts*

Although electromagnetic emission from GRBs is widely observed down to the radio, the VHE domain remains largely uncharted. The transient and unpredictable nature of GRBs combined with intrinsic alert delays by X-ray satellites, makes it difficult for IACTs to observe GRBs rapidly enough to catch the prompt-to-early afterglow phases in which very-high-energy emission is either rarely, or as yet not observed. However, SWGO's wide field of view, large, unbiased duty cycle, and sensitivity $\lesssim 1$ TeV would allow for the monitoring of all nearby GRBs inside its field of view, increasing the number of observations without the need for external triggers, in addition to the benefits of its archival data analysis (see Figure 3). Additionally, follow-ups in SWGO's energy range would potentially allow for the discrimination between proposed emission scenarios— a longstanding topic of great interest within the field.

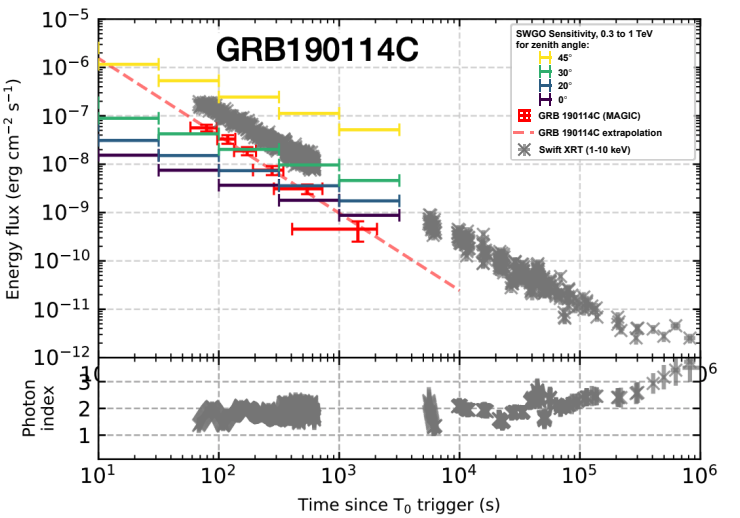

Fig. 3. SWGO's sensitivity to a GRB like GRB 190114C, including results from the MAGIC telescopes for comparison. Figure adapted from Ref. 10.

3.2. *Galactic Particle Acceleration*

The study of very-high-energy gamma rays is one of the most powerful methods to search the Galactic plane for astrophysical particle accelerators, including PeVatrons— sources able to accelerate hadrons up to the "knee" of the cosmic-ray spectrum. With its large energy range, excellent sensitivity above 10 TeV, and ideal design features, SWGO will be able to isolate Galactic PeVatrons from the background of softer gamma-ray sources. Its design means that SWGO is well equipped to handle the source confusion, diffuse gamma-ray backgrounds, and spatially extended emission regions that typically complicate these kinds of analyses, making its sensitivity to astrophysical particle accelerators in the local Galactic neighborhood one of the greatest strengths of the proposed observatory. From this, we are enthusiastic that SWGO will be the optimal instrument to discover sources such as the microquasar SS433.[11] Such assets will also allow SWGO to identify hard-spectrum sources for long-term observation with CTA, as well as complement the coverage provided of the Northern Hemisphere by HAWC and LHAASO.

3.3. *Pulsar Wind Nebulae and Gamma-Ray Halos*

First observed by HAWC,[12] the all-sky observations of which SWGO is capable will allow the testing of large gamma-ray halos as potential sources of the observed positron excess. Studying gamma rays from such potential positron sources provides crucial input to the positron excess puzzle. SWGO will survey nearby pulsars (age $< 10^6$ yr; see Figure 4) in the Southern Hemisphere, where its wide field of view is ideal for measuring gamma-ray halos around the co-located pulsar wind nebulae (PWNe), including from millisecond pulsars not (yet) discovered with current instruments. The large extents of these gamma-ray halos allow us to study the propagation of particles within them in unprecedented detail, unveiling the properties of the accelerators and the medium around them.

3.4. *The Extragalactic Very-High-Energy Sky*

Several models currently exist to explain the spectra of Active Galactic Nuclei (AGN) from radio to very-high-energy gamma rays, with additional data needed to unravel the mechanisms at work in these extreme environments. The very-high-energy extragalactic sky is dominated by Blazars, radio-loud AGN with jets oriented near our line of sight, whose second power-spectrum peak in the gamma rays has a much debated origin. SWGO is expected to be able to detect very-high-energy blazars at both short and long time scales, as well as perform searches in an unbiased way over the full Southern sky due to its near-continuous duty cycle. Such observations will provide information on the intergalactic magnetic field, radiative processes and acceleration mechanisms, periodicity, and beyond-the-Standard-Model physics. SWGO's characteristics are also ideal for the crucial evaluation of the significance of neutrino-blazar flare correlations, such as implied by observations of TXS 0506+056.[13]

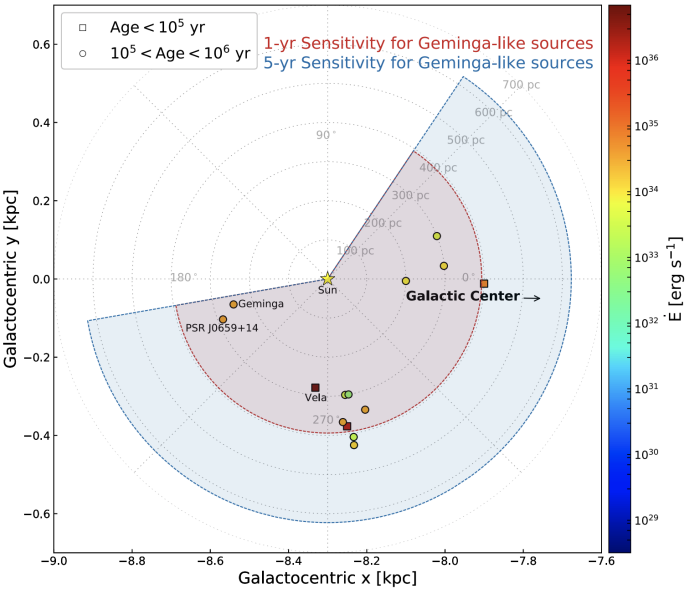

Fig. 4. Pulsars, age $< 10^6$ yr., within 500 pc, showing the one-year (red) and five-year (blue) sensitivity of SWGO to Geminga-like sources at these locations. Figure from Ref. 1.

3.5. *Physics Beyond the Standard Model*

Returning to the sky that we would expect to see with SWGO in Figure 5, one can see that SWGO would have access to several prominent dark matter targets that cannot be seen, or cannot be seen well, by HAWC in the Northern Hemisphere, such as the Galactic Center, the Magellanic Clouds, and a population of dwarf galaxies recently discovered with optical surveys like DES.

3.5.1. *WIMP Searches with Cosmic Gamma Rays*

Dark matter annihilation is theorized to produce Standard Model particles through weak interactions which, in turn, produce gamma rays, mainly via pion decay but also through inverse Compton scattering of photons off produced electron-positron pairs. Weakly Interacting Massive Particles, or WIMPs, are promising dark matter candidates with $E_{CM} \sim 100$ GeV. Their masses can range from $\sim$5–100 TeV, but the heaviest particles, $m_\chi > 10$ TeV, that can only be searched for with an instrument with a high sensitivity, are best probed with an indirect experiment like SWGO. Heavy dark matter (100 TeV–100 PeV) is also theorized beyond the WIMP model, where SWGO's wide field of view and sensitivity to the highest energies will make it a crucial player in searching for indirect signals from dark matter.

The Galactic Center is the closest dense region of dark matter and, as seen in Figure 5, SWGO's location in the Southern Hemisphere will allow this to be a prime

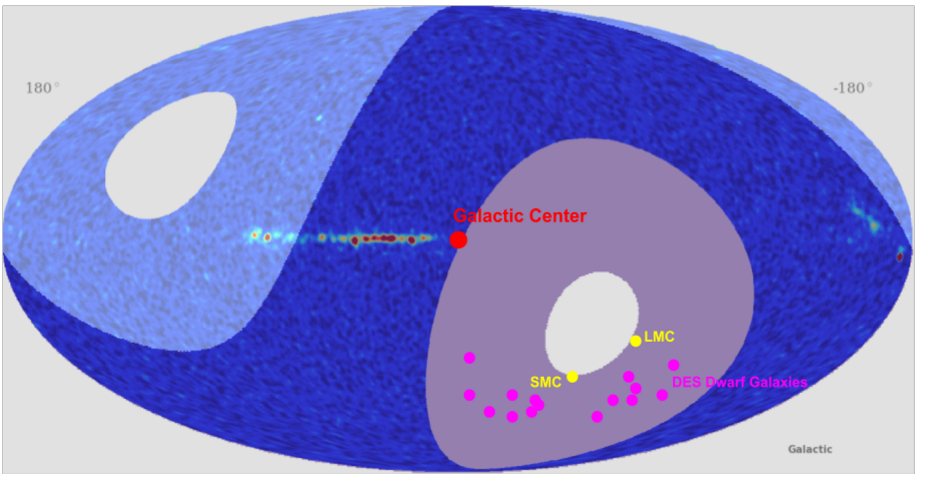

Fig. 5. HAWC skymap with SWGO view (shaded) overlaid. Figure from Andrea Albert.

target for observations. This is also an opportunity to highlight the complementarity of SWGO with the *Fermi*-LAT and CTA. Combined, these experiments will explore thermal WIMPs from 5 GeV–100 TeV.[14] There is an overlap in mass between experiments, which will allow for multiple potential detections, but it is SWGO that extends the reach of such studies up to 100 TeV— one of many exciting reasons to build SWGO.

3.5.2. *Axion-Like Particles*

As SWGO will have its best sensitivity at the highest energies, we can also look for Axion-like particles (ALPs), a generalization of the axion and a well-motivated dark matter candidate. Gamma rays from AGN can convert to ALPs in magnetic fields in the environment through which they propagate. These particles can travel unattenuated through the extragalactic background light (EBL) and convert back into gamma rays in the Milky Way's magnetic field. This conversion results in a high-energy tail in the observed energy spectrum—as seen in Figure 6—to which SWGO would be sensitive.

3.5.3. *Dark Matter Searches in Dwarf Galaxies*

We can also look for dark matter annihilation gamma rays from dwarf galaxies, many of which have recently been discovered by optical surveys in the Southern Hemisphere, making them prime targets for SWGO. These dwarf spheroidals (dSphs) are dark-matter-rich Milky Way satellites that are nearby and essentially background-free. With its wide field of view and large duty cycle, SWGO will observe dozens of dSphs every day, giving us the ideal survey of the sources needed

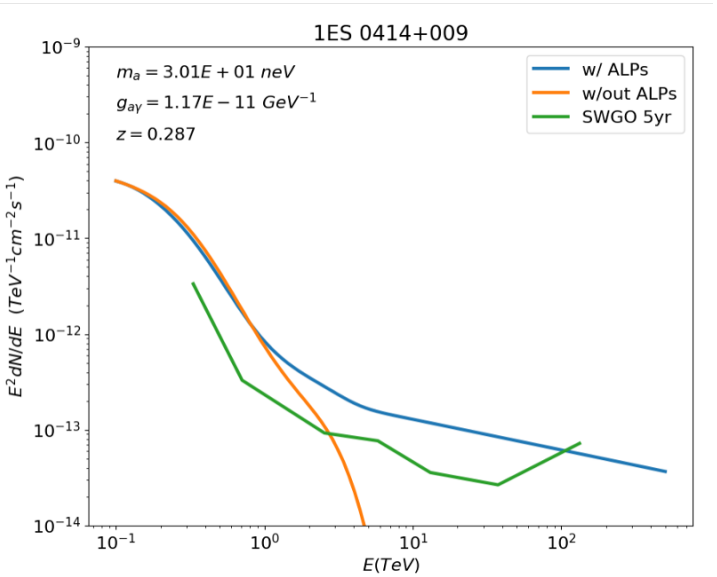

Fig. 6. ALP conversions could produce sharp spectral features in the observed spectrum of extragalactic sources which would require good energy resolution and large event statistics to resolve well. Figure from Ref. 1.

to place strong constraints on dark matter annihilation and decay. Unlike similar experiments, SWGO will have archival data at all locations within its field of view, which means if a new dwarf is discovered, there is already data on it to be analyzed with no time delay to collect it, such as might be experienced with IACTs.

3.5.4. *Lorentz Invariance Violation*

If Lorentz Invariance is violated, then gamma rays above an energy threshold ($E^{(n)}_{LIV}$) rapidly decay into e^+e^- pairs, so seeing a photon at the highest energies will set a limit on the energy scale of Lorentz Invariance Violation (LIV)— The current highest gamma-ray energy observed is 1,140 TeV seen by LHAASO.[15] SWGO's sensitivity up to several PeV would allow gamma rays to be probed for this signature of LIV at the highest energies ever observed. The detection of multiple PeV gamma rays will provide the world-leading constraints on LIV.

3.5.5. *Primordial Black Holes*

Primordial Black Holes (PBHs) are black holes created in the early Universe with masses ranging from the Planck mass to supermassive black holes. PBHs in some mass ranges are candidates to constitute some of the observed dark matter in the Galaxy. PBHs evaporate through Hawking Radiation, with this evaporation increasing substantially towards the end of their lives, producing a burst of very-high-energy gamma rays. As these are transient sources with a runaway emission,

SWGO's wide field of view and large duty cycle make it an optimal instrument with which to observe PBHs of initial mass $m_{PBH} \sim 5 \times 10^{14}$ g. The expected limits are 30 times better than the data-based limits currently placed by HAWC,[16] as shown in Figure 7.

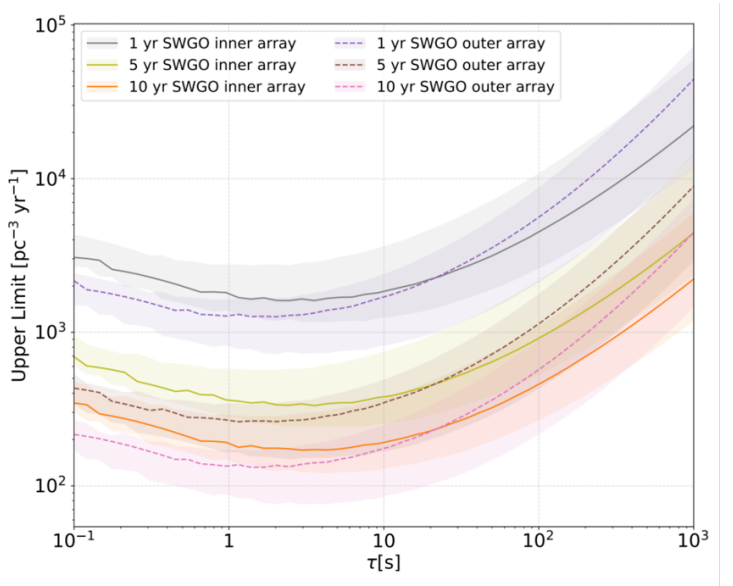

Fig. 7. The expected limits on the local burst rate density of PBHs. Figure from Ref. 17.

3.6. *Cosmic Rays*

The main feature in the energy spectrum of Galactic cosmic rays is the so-called "knee", which is characterized by a steepening of the spectral index from ~ -2.7 to ~ -3.1 at about 3 PeV. Understanding the origin of the "knee" is the key for a comprehensive theory of the origin of cosmic rays up to the highest observed energies. SWGO is uniquely suited to detect sources of cosmic rays with energies in excess of 1 PeV—expected to produce very-high-energy gamma rays above 100 TeV[18–21]—and measure any cutoffs in their spectra that indicate the maximum energy to which they are able to accelerate particles. With its wide aperture and its almost 100% duty cycle, SWGO will be able to gather significantly larger electron event statistics than IACTs, which may help in extending the electron spectrum further than the 20 TeV already measured, potentially revealing more details of the local source distribution. Additionally, the large sky coverage of SWGO would enable the search for anisotropy in the electron arrival direction at different angular scales, which would provide additional very relevant information for the understanding of Galactic particle acceleration and cosmic-ray transport.

4. Looking Forward

As a ground-based cosmic-gamma-ray observatory sensitive up to PeV energies, SWGO would be the most sensitive gamma-ray observatory in the Southern Hemisphere above 10 TeV, with complementarities among both Northern Hemisphere observatories, as well as other Southern Hemisphere observatories. With its wide field of view, near 100% duty cycle, ad high-energy reach, SWGO will provide the world's best sensitivity to emission from high-energy transients, propagation of particles within gamma-ray halos, PeVatrons in the galactic plane, several dark matter candidates, and Lorentz Invariance Violation.

Hard X-/soft Gamma-ray astronomy is a key field for the study of important astrophysical phenomena such as the electromagnetic counterparts of gravitational waves, gamma-ray bursts, black holes physics and many more. However, the spatial localization, imaging capabilities and sensitivity of the measurements are strongly limited for the energy range >70 keV due to the lack of focusing instruments operating in this energy band. A new generation of instruments suitable to focus hard X-/ soft Gamma-rays is necessary to shed light on the nature of astrophysical phenomena which are still unclear due to the limitations of current direct-viewing telescopes. Laue lenses can be the answer to those needs. A Laue lens is an optical device consisting of a large number of properly oriented crystals which are capable, through Laue diffraction, of concentrating the radiation into the common Laue lens focus. In contrast with the grazing incidence telescopes commonly used for softer X-rays, the transmission configuration of the Laue lenses

allows us to obtain a significant sensitive area even at energies of hundreds of keV. At the University of Ferrara we are actively working on the modelization and construction of a broad-band Laue lens. In this work we will present the main concepts behind Laue lenses and the latest technological developments of the TRILL (Technological Readiness Increase for Laue Lenses) project, devoted to the advancement of the technological readiness of Laue lenses by developing the first prototype of a lens sector made of cylindrical bent crystals of Germanium.

Keywords: Hard X/soft Gamma-ray astronomy; Laue Lenses; Focusing Telescopes.

1. Laue lenses: A new way to look at the X-ray/Gamma sky

Laue lenses are innovative X and Gamma-ray optics based on the Bragg's law of diffraction in crystals[1]:

$$2d_{hkl} \sin \theta_B = n \frac{hc}{E} \tag{1}$$

Where θ_B is the Bragg's angle, which is the angle between the diffraction planes of the crystal and the diffracted beam, d_{hkl} is the inter-planar spacing of diffraction planes of the crystal with Miller indexes (hkl), E is the energy of the diffracted photon, n is the diffraction order and hc corresponds to 12.4 keV · Å.

The crystals can be arranged in such a way that the X-ray beam can be reflected by a thin, superficial layer of the crystal (Bragg geometry, or Reflection geometry) or it can cross the whole crystal and be transmitted over it (Laue geometry, or Transmission geometry).

Optics based on Bragg's law of diffraction in Laue configuration can be of great interest in the astrophysical context because (1) Bragg's diffraction is effective up to energies of few MeV and (2) the transmission configuration can be exploited to increase the effective area of the optics.

A Laue lens, indeed, is exactly based on this concept. A Laue lens can be visualized as a spherical cap of radius R covered by crystal tiles oriented in such a way that the the radiation coming from the sky is transmitted through the crystals and sent to the focal point. The focal distance of the lens f is equal to half the curvature radius of the spherical cap[2] (Fig. 1).

There are different configurations for the crystals on the cap which can be chosen to optimize the effective area in different ways; the simplest one, which is the configuration we are using for our prototypes, is to place the crystals in concentric rings at a distance r from the axis of the lens. From the Bragg's equation, we can see that the centroid of the energy spectrum of the photons diffracted by each ring can be expressed as[2]:

$$E = \frac{hc}{2d_{hkl}} \sin \left[\frac{1}{2} \arctan \left(\frac{f}{r} \right) \right] \sim \frac{hc}{d_{hkl}} \frac{f}{r} \tag{2}$$

Where the approximation holds for small Bragg's angle, which is the case of hard X and Gamma rays. Higher energy photons are diffracted from crystals in the inner region of the lens, while lower energy photons interact with the outermost regions

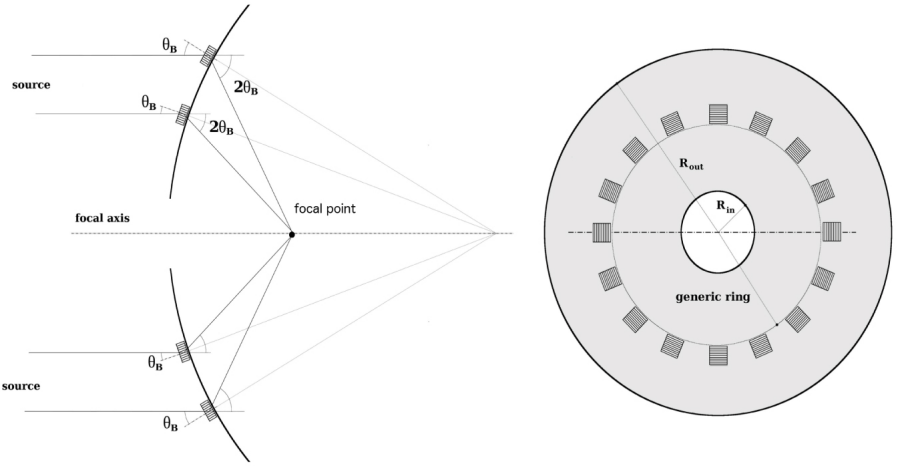

Fig. 1. Side and top view of a Laue lens. The crystals are positioned on a spherical support in such a way that the radiation coming from the sky, parallel to the optical axis of the lens, interacts with the crystals and is focused. The diffraction planes of the crystals are oriented in such a way that the angle between them and the incoming X-ray beam is equal to the Bragg's angle θ_B, so the angle between the diffracted beam and the incoming beam is $2\theta_B$. The focal lens is equal to half the curvature radius of the spherical cap.

of the optics (Fig. 2). With Laue lenses, we expect to be able to build a lightweight (<150 kg), stable optics which will enable real concentration of high energy radiation up to 600 keV at a focal distance of 20 m. Thanks to the unprecedented imaging capabilities of Laue lenses, we will be able to obtain a Point Spread Fuction (PSF) with a width of ∼30 arcsec in the energy band 50 keV - 600 keV. Comparing this with one of today's most advanced high energy instruments, the IBIS aboard INTEGRAL, whose PSF is of about 12 arcmin we can immediately understand the quantum leap in imaging capabilities that would be brought by an instrument such as a Laue lens, which will also allow us to make spectroscopy and even X-ray Compton polarimetry with an unprecented quality.

2. Bent perfect crystals

Several types of crystals can be used to build a Laue lens and the imaging capabilities and effective area of the optics are strictly related to the physical and chemical nature of the chosen crystals. Two are the families of crystals that we considered for our applications: perfect crystals and mosaic crystals.

A perfect crystal is a crystal in which the lattice plane are all oriented in the same direction. The rocking curve of the crystal has a Gaussian shape and it centered on the position satisfying Bragg's equation. The Full Width at Half Maximum (FWHM) of the rocking curve is called Darwin width.[1] A mosaic crystal, instead, can be seen as made up by microscopic perfect crystals, called *crystallites*, whose

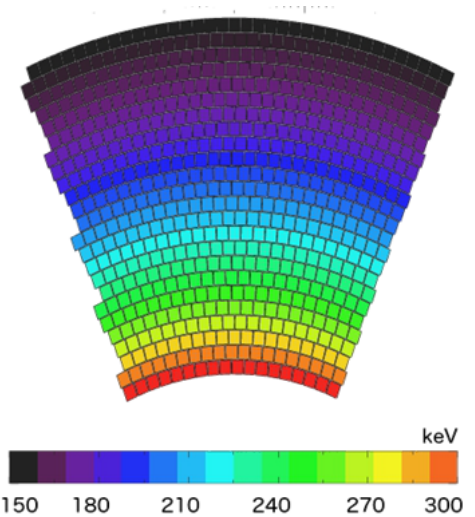

Fig. 2. In a spherical Laue lens, all the crystals at the same radial distance from the center of the lens are sensitive to the same energy range, so by nesting multiple rings it is possible to build a broad-band Laue lens. The highest energies are focused by the innermost crystals, while the lower energies are focused by the outermost crystals.

diffraction planes are misaligned around an average direction following a Gaussian distribution. The FWHM of the distribution of the cristallites is called *mosaicity* of the crystal.[1] The presence of a distribution of cristallites increases the passband of the crystals, however it also generates an effect called *mosaic defocusing*, which enlarges the PSF.

With the past HAXTEL project,[3] flat mosaic crystals of copper crystals were successfully used to build a prototype of a short-focal Laue lens. However they show some evident limits:

- Flat crystals don't have true concentration capability: they can redirect X-ray beams, however the size of the image produced by a flat crystal is comparable to the cross section of the crystal itself. This can be a problem especially in the case of long-focal lenses, for which very small crystals would be required to obtain an adequately small image.
- Flat crystals, expecially of the perfect type, show a very narrow passband.[1] Even though they can work perfectly for a narrow band Laue lens, the reduced pass-band is a problem for a broadband Laue lens, since it can be responsible of a very uneven variation of the effective area of the instrument.
- The diffraction efficiency for flat crystals cannot be higher than 50%.[1] This comes from the fact that the photon traversing the crystal have the same probability of undergoing an even or odd number of diffraction processes, limiting the maximum efficiency theoretically achievable.

The use of bent crystals allow us to overcome those limitations. A bent crystal is a crystal in which the average direction of the diffraction planes varies inside the volume of the crystals according to a definite curvature radius. If a crystal is cilindrically bent, which is the easiest type of curvature configuration attainable, then it acts as a concentrator along the bent direction, focusing the radiation coming from an astrophysical source to a focal distance equal to half the curvature radius of the crystal itself.[4] This allows us both to shrink the cross section of the image in a region smaller than size of the crystal tile, and to increase the energy passband of each crystal (Fig. 3).

This holds true both for perfect and mosaic crystals, however bent perfect crystals have some interesting properties which can make them particularly interesting for a Laue lens.

Bending a perfect crystal to a chosen curvature radius induce an internal secondary curvature on specific diffraction planes in a way related to the primary curvature radius of the crystal.[5] In this way, the average direction of the diffraction planes varies continuously inside the crystal, slightly increasing their angular spread, whose average value is called *quasi-mosaicity* of the crystal.[6]

According to the dynamical theory of diffraction in bent perfect crystals, the bending of a perfect crystal can also increase the reflectivity of the bent planes above the limit of 50%.[5] This can be explained intuitively in the following way: since the diffraction planes are curved, the probability that the beam crossing the crystal

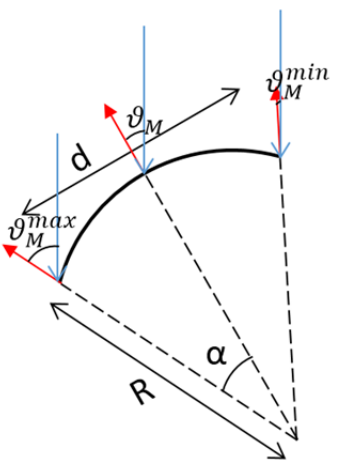

Fig. 3. Explanation of the concentration effect given by cylindrical bent crystal: due to the fact that the crystal is bent, the average direction of the diffraction planes (red arrows) varies continuously inside the crystals, which means that the Bragg's angle of the incoming radiation (blue arrows) changes accordingly. The result is that the X-ray beam is concentrated and that the crystal's energy pass-band is enlarged of a quantity which depends on the length of the focusing direction d of the crystal, its curvature radius R and its average diffracted energy.

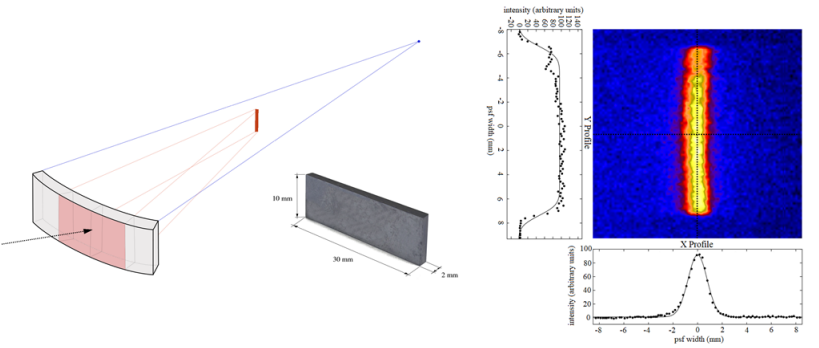

Fig. 4. Right: Schematics of the concentration effect of one cylindrical bent, 30×10 mm^2 crystals such as the one used in our tests. The radiation (in red) is concentrated along the focusing direction and the image is produced at a distance equal to half the curvature radius of the crystal. Left: Experimental image of a concentrated 150 keV X-ray beam obtained at the LARIX Facility. The area of the crystal is of 30×10 cm^2, while the area of the image is of 0.1×10 cm^2, which means that the beam was concentrated in an area 30 times smaller than the size of the crystal itself.

undergoes further diffractions gets reduced in a significant way. Experimental results suggest that an increase of the reflection efficiency can be effectively achieved.[7]

A crystal can be curved in an elastic way, by applying mechanical clamps to its surface, or in a plastic way, by subjecting it to a permanent deformation.[8] A mechanical bending of the crystal can bring some excessive complications for an astrophysical Laue lens, since adding further mechanical parts would increase the weight of the optics, the complexity of the design and the opacity to radiation, so crystals permanently bent are required for this type of applications.

Different methods to obtain a self-standing, cylindrical curvature have been studied and the surface lapping technique, developed at the IMEM/CNR in Parma, is one of the methods that reached a good technological maturity[9].[10] This technique consists in inducing a controlled damage by lapping one of the surfaces of the crystals, which generates an internal strain able to bend the crystal in self-standing way. The parameters of the lapping process, such as the grain of the machine, the sanding time and the final thickness of the crystals after the lapping procedure, can be set to bend the crystals to the desired curvature radius. The process can be paired with an etching process which can be used to reduce an excess of the curvature radius. By combining both methods, the curvature radius of the crystal can be fine-tuned in a very precise way. The focusing capabilities and the pass-band increase of crystals bent by surface lapping have been experimentally confirmed at our facility.[11]

For our prototype of Laue lens, we aim to use bent perfect crystals of Silicon and Germanium. Past tests done with mosaic GaAs(220) crystals curved to a radius of 40 m showed that bent crystals are able to focus high energy X-rays (Fig. 4). Now that the focusing capabilities of bent crystals has been widely assessed, we are moving to perfect Si(111) and Ge(111). According to the dynamical theory of

diffraction, the (111) planes will show the properties of increased efficiency described by Malgrange's theory of bent perfect crystals.

3. The TRILL project

The TRILL project (Technological Readiness Level Increase for Laue Lenses) is a project funded by the Italian Space Agency (ASI) for the increase of the Technological Readiness Level (TRL) of technologies with a potential use in future space missions. The aim of the TRILL project is to increase the TRL of a Laue lens in all its aspects, from the production of the crystals, to their integration on the lens itself, to the performance testing using an adequate spectroscopic-imager detectors used as focal plane detectors.

To build our first prototype of Laue lens, we decided for a modular approach: the full Laue lens in divided in spherical sectors called *petals* and each petal is then divided in smaller *modules*. Every module can host some tenth of crystals (Fig. 5). Aim of the TRILL project is to build 4 modules of a Laue lens and join them together in a first prototype of a subsector of a petal.

The TRILL project is structured on the following main tasks:

(1) To define a reliable and repeatable way to bend the crystals with no deterioration of their properties. To avoid distortion on the PSF of the single crystals, it is crucial that the curvature radius of the bent Si and Ge crystals is as uniform as possible and within an accuracy of ± 2 m from the desired curvature radius of 40 m.
(2) To find the best materials and bonding method to build a module of Laue lens. To reach the desired PSF size of 30 arcsec, we need that the crystal tiles are

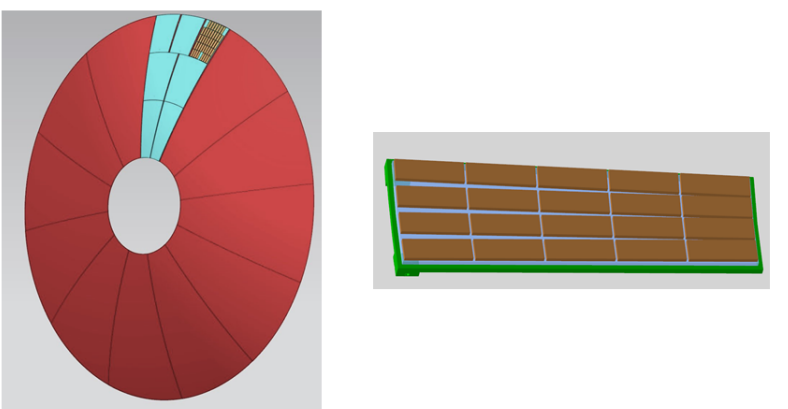

Fig. 5. Left: Schematic CAD model of a full Laue lens. The lens is divided in spherical sectors, called petals (red), and each petal is divided in a series of modules (cyan). The crystals are fixed on each module. Right: CAD model of a module of Laue lens, with 20 crystals on top.

set with an accuracy better than 10 arcsec, which requires us to find a very fine way to position the crystals.

(3) To find a way to join the modules together in one single piece. The modules will be connected in a way that will grant the possibility to adjust the position of each piece in an active way, to allow us to correct the position of the modules whenever required.

In this section, we illustrate the status of advancement of each of those 3 tasks.

The manufacturing of the crystals is done at the CNR/IMEM in Parma. Here, the crystals of Silicon and Germanium that we want to use for our prototypes are cut from wafers to obtain $30 \times 10 \times 2$ mm^3 tiles. Each tile is then bent via surface lapping to the desired curvature radius of 40 m. The procedure in the past was first tested on mosaic GaAs(220) crystals with a mosaicity of 13 arcsec. From those previous tests, we discovered that there is range of values for the crystal curvature radius for which the distortion of the image induced by a distorted curvature radius is completely masked by the mosaic defocusing effect. This allows us to reduce the constraints on the accuracy of the curvature radius of the crystals according to the value of the angular dispersion of the diffractive planes.

In the case of perfect Ge(220) crystals, the lapping procedure generates a mosaic structure on the diffraction planes of the crystals, which acquire a mosaicity of $\sim$5 arcsec. Given this value of mosaicity, if the curvature radius of the crystals is within $\pm$2 m from the nominal value of 40 m, the induced distortion on the PSF is negligible.

Last tests on Ge(220) gave very promising results: the values of the curvature radius of this first sample of 38 Ge(220) crystals were in the range [37.9 $\pm$ 0.9;

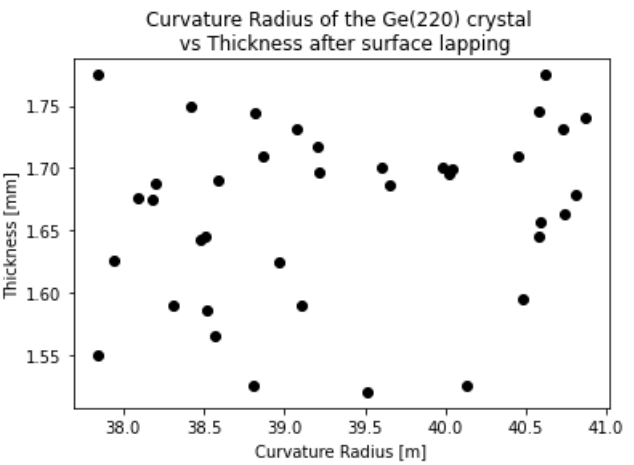

Fig. 6. Curvature radius of the sample of 38 bent crystals of Ge(220) vs their thickness after the surface lapping procedure. All the curvature radius are in the limit $\pm$2 m from the nominal curvature radius of 40 m.

40.9 ± 0.7] m, which means that every crystal is suitable for our applications. The average value of the curvature radii distribution is of 39.3 ± 0.2 m, with a standard deviation of 1 m (Fig. 6).

The lapping procedure, however, removes part of the material and the thickness of the crystals gets significantly decreased. The final thickness of the crystals after the lapping procedure is in the interval [1.520 ± 0.005; 1.775 ± 0.005] mm, with an average value of (1.665 ± 0.002) mm (Fig. 6).

The module assembly is the second, crucial task of the TRILL project. The crystals will be bonded on an adequate substrate. Ray-tracing simulations of a full Laue lens made by bent perfect crystals of Ge(111) allowed us to establish that it is necessary a positioning accuracy of the crystals'diffracting planes <10 arcsec to obtain the desired PSF accuracy of 30 arcsec for the full lens. Given that the focal length of the lens is of 20 m, this required accuracy translates in a positional accuracy of the crystals of the order of few microns, which means that high precision bonding techniques are required to integrate the crystal on the support of the prototype.

Currently each Laue lens module consists of a glass trapezoid substrate on which the crystals are glued with a low-shrinkage UV-curable glue. Each substrate is made of clear quartz, chosen due to its transparency and its low CTE. The substrate is shaped as an isosceles trapezium with bases 68 mm and 56 mm long, while the height is 183 mm. Given that the cross section of the crystals is 30×10 mm^2 and that the spacing between the crystals glued on the substrate will be of about 1 mm, each glass support can hold about 30 crystals. The surfaces of the substrate was bent to a curvature radius of 40 mm, the same of the crystals, at the National Institute of Optics of the National Research Council, in Florence. The substrate is hold in vertical position by an INVAR steel frame.

The crystals are positioned on the glass substrate using a motorized hexapod with six degrees of freedom: three translations and three rotations. The hexapod has a accuracy of the order of 1 micron on the translational movements and of 2×10^{-5} radians on the rotations (Fig. 7, left).

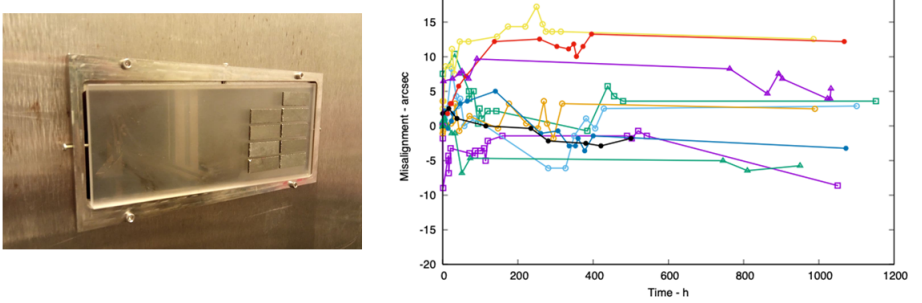

Fig. 7. Left: Laue lens module with nine crystals glued on top. The steel frame supporting the glass substrate is visible. Right: Misalignment of the crystals vs time from bonding.

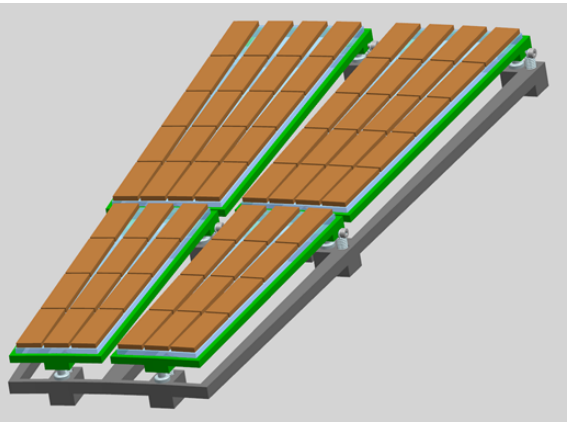

Fig. 8. CAD model of the four Laue lens module assembled. The module will be connected to a steel frame by means of micrometric screws.

The glue currently used to bond the crystals to the glass substrate is the *DYMAX OP-61-LS*, an UV curable, single component optical adhesive. This glue was choosen for its very low linear shrinkage of 0.03% of its length and for its high viscosity, which makes it suitable for a vertical bonding.

The crystals are glued with the following procedure: (1) the crystal is positioned on the hexapod and oriented to the proper Bragg's angle, then (2) a small drop of glue is deposited on the substrate with a glue dispenser, (3) the crystal is then put in contact with the glue and the position is fine tuned to correct eventual slight change in the position of the crystal, (4) the glue is cured with an UV lamp and finally (5) the crystal is released from the hexapod.

The position of the crystals is then tested immediately after the bonding and also when some time has passed. We found that the misalignment of the crystals after 50 days from bonding is within the interval +15/-10 arcsec (Fig. 7, right). These first results are quite good, since we are starting to get close to our target of <10 arcsec misalignment. However at the moment this technique shows some problems of stability in time and repeatibility. In particular, we are studying a better way to measure the quantity of glue deposited on the substrate and to control the illumination uniformity of the UV light used for the curing process.

The last task, i.e. the study of a way to assemble the modules together, is currently in study phase. At the moment, we plan to join the modules together by building a metal support frame in which the different modules will be fixed with high precision micrometric screws (Fig. 8). The screws will be set in position by using miniaturized piezoelectric motors, which will allow us to actively change the orientation of the module in any moment and to reduce as much as possible the effect that external solicitation can have on the final alignment of the prototype and, latter, of the full Laue lens itself.

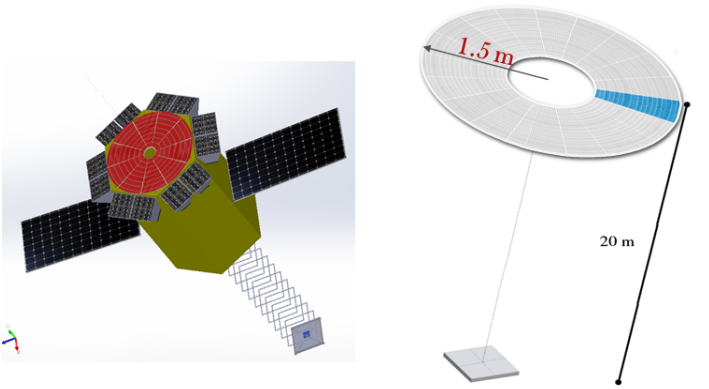

Fig. 9. Left: Representation of ASTENA's in-flight configuration. The Laue lens is shown on the top of spacecraft, in red. Right: Schematic representation of NFT. NFT will be made by a Laue lens optics with 3 m of diameter and 20 m of focal length. The focal plane detector will be a CZT spectral-imager detector.

The next step of the TRILL project will be to start the production of the bent Si(111) and Ge(111) crystals, to further optimize the bonding process and build the 4 modules and, finally, to assemble the modules together.

4. The NFT aboard ASTENA

Our studies on Laue lenses, including the TRILL project, are oriented to develope the technology for building the Narrow Field Telescope (NFT) on-board ASTENA, the Advanced Surveyor for Transient Events and Nuclear Astrophysics, a concept mission that we proposed for the ESA Call "Voyage 2050"[12].[13] The Narrow Field Telescope will be a revolutionary hard X/soft Gamma-ray focusing telescope working in the energy band 50-700 keV based on the technology of Laue lenses (Fig. 9). The NFT will be made by a Laue lens optics of 3 m of diameter with 20 m focal length. The lens will be made by about 19500 crystal tiles of perfect Si(111) and Ge(111) of size $30\times10\times2$ mm^3, bent to a curvature radius of 40 m. In the context of the TRILL project, we will then test the capabilities of the crystals that will be used for the lens and define the construction method for the whole lens.

The assumed focal plane detector will be a pixelated CdZnTe spectral-imager detector, with a size of $8\times8\times8$ cm^3, a pitch of 300 μm and an efficiency >80% in the whole energy band of NFT.

The combination between the characteristics of the optics and the detector will grant NFT of an unprecedented angular resolution in the sub-MeV energy range of 30 arcsec and a point source localization accuracy <10 arcsec, with a Field of View of 4 arcmin. NFT will bring a leap in sensitivity of two order of magnitude with respect to the best current instruments working in the same energy bands, opening a new range of possibilities for high energy astronomical observations.

Gamma-ray astronomy is a branch whose potential has not yet been fully exploited. The observations of elemental and isotopic abundances in supernova (SN) explosions are key probes not only of the stellar structure and evolution but also for understanding the physics that makes Type-Ia SNe as standard candles for the study of the Universe expansion properties. In spite of its crucial role, nuclear astrophysics remains a poorly explored field mainly for the typical emission lines intensity which are vanishing small and requires very high sensitivities of the telescopes. Furthermore, in spite that the Galactic bulge-dominated intensity of positron annihilation line at 511 keV has been measured, its origin is still a mystery due to the poor angular resolution and insufficient sensitivity of the commonly employed instrumentation in the sub-MeV energy domain. To answer these scientific issues a jump in sensitivity and angular resolution with respect to the present instrumentation is required. Conceived within the EU project AHEAD, a new high energy mission, capable of tackling the previously mentioned topics, has been proposed. This concept of mission named ASTENA (Advanced Surveyor of Transient Events and Nuclear Astrophysics), includes two instruments: a Wide Field Monitor with Imaging and Spectroscopic (WFM-IS, 2 keV - 20 MeV) capabilities and a Narrow Field Telescope (NFT, 50 - 700 keV). Thanks to the combination of angular resolution, sensitivity and large FoV, ASTENA will be a breakthrough in the hard X and soft gamma–ray energy band, also enabling polarimetry in this energy band. In this talk the science goals of the mission are discussed, the payload configuration is described and expected performances in observing key targets are shown.

Keywords: Soft gamma-rays; hard x-ray telescope; Focusing gamma rays; Bragg diffraction; bent crystals.

1. Introduction

Within the H2020 European program AHEAD,[1,2] (integrated Activities for High Energy Astrophysics Domain) devoted to the assessment of future gamma-ray experiments, a Scientific Advisory Group recommended the prime scientific questions that might be addressed by a future space mission operating in the gamma-ray energy domain. The high-priorities themes resulted to be the nuclear astrophysics and

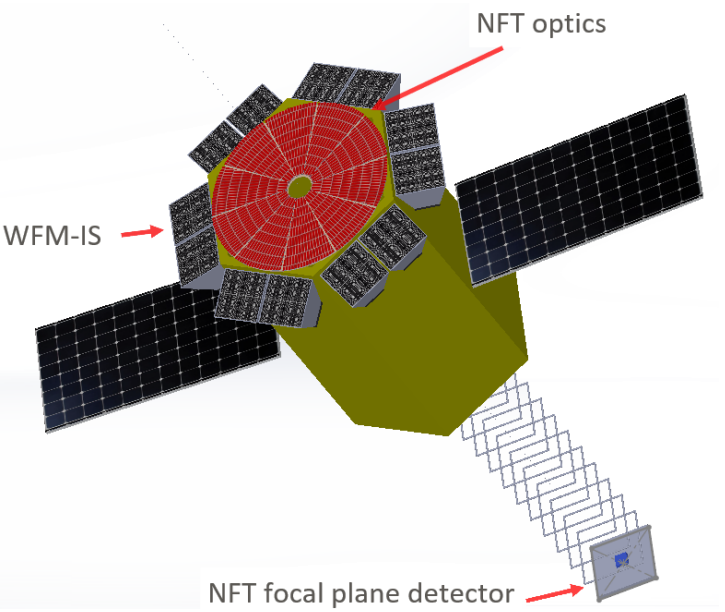

Fig. 1. Drawing of the ASTENA mission. The NFT (in red) is a 20 m focal length Laue lens made with bent Germanium and Silicon crystals. At the focal distance is positioned a focal plane detector (blue) which is a solid state device made with 4 layers of Cadmium Zinc Telluride. The focal distance is achieved through a deployable mast which at launch is fully enclosed in the spacecraft and in operative condition extends from the bottom of the spacecraft for 15 m, which is a reasonable distance for the stability of an extendable structure. The WFM-IS composed of 12 Position Sensitive Detectors (PSDs) distributed around the NFT and oriented 15 degrees two by two outwards with respect to the Laue lens axis in order to extend the FoV of the overall instrument.

the study of the transient sky. According to those themes, the ASTENA (Advanced Surveyor for Transient Events and Nuclear Astrophysics) has been designed. The ASTENA concept mission, which is shown in Fig. 1, is a broad energy pass-band experiment composed by two complementary instruments. The first is a Wide Field Monitor with Imaging and Spectrometric capabilities (WFM-IS) with an outstanding broad energy pass-band from 2 keV to 20 MeV. It consists on 12 coded mask cameras deployed in a circular pattern around the hexagonal spacecraft and oriented at 15 degrees with respect to the spacecraft axis. The overall Field of View (FoV) of the instrument is $\sim$2 steradians. The second instrument is a narrow FoV (few arcminutes) telescope based on a Laue lens with a geometric area of $\sim$7 m^2 and 20 m focal length, capable to focus photons in the broad energy pass-band 50 - 700 keV on a solid state detector. The Narrow Field Telescope (NFT) represents a technological breakthrough as its optics, based on the diffraction from bent crystals, provides an unprecedented sensitivity with respect to any other mission flown and operative in the same energy pass-band. At launch, we expect to keep the WFM-IS cameras and the focal plane detector stored within the cylindrical spacecraft

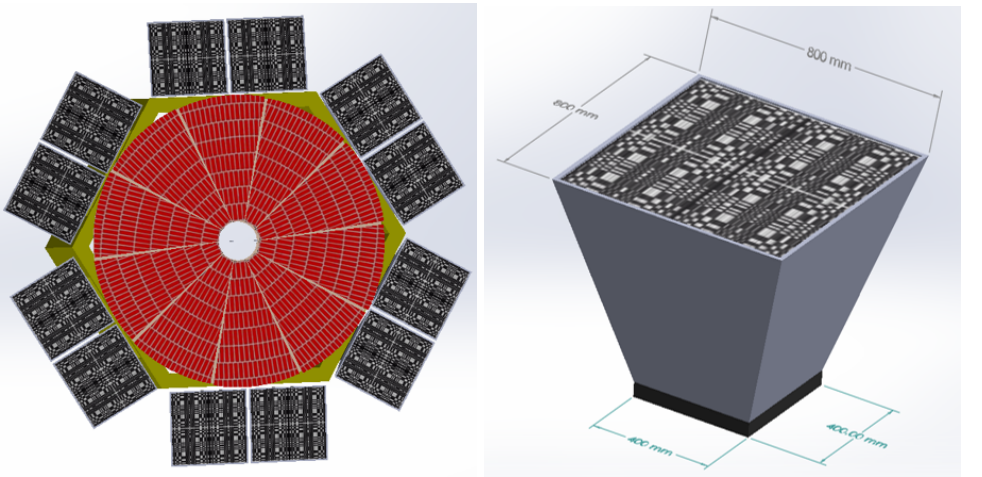

Fig. 2. Left: Top view of the instruments on board ASTENA. The 12 PSD of the WFM/IS are coupled 2 by two and are positioned around the hexagonal structure of the spacecraft. Each PSD is surmounted by a coded mask which ensures the imaging capability up to 150 keV. The red part is the broad energy pass-band Laue with 15 m focal length. Right: Detail of one PSD in which is visible the coded mask and the collimator surrounding the instrument. At the bottom (dark profile) is visible the detection plane made with scintillator bars which are coupled with SDDs (see text for the explanation of the instrument working principle).

whose diameter is 1.5 m and the length is 5 m. In the operational configuration an extendable boom brings the focal plane detector 15 m apart from the bottom of the spacecraft while a mechanism discloses and tilts the coded mask cameras at their nominal position and angle. In the following currently on-going project called AHEAD2020 the mission concept is being refined and optimized. The mission has been proposed in the ESA call "Voyage 2050"[3] as a future medium class mission for hard X-/soft gamma-ray astrophysics.[4,5] The final recommendation of the Senior Committee has confirmed the key importance of the high energy observations from space with high sensitivity and capable of enabling spectro-polarimetry based on new technologies, particularly in synergy with gravitational wave astronomy for resolving some of the fundamental questions still unanswered in astrophysics related to the nucleosynthesis in explosive events or to the accretion mechanism on compact sources.

2. The ASTENA configuration

The ASTENA mission concept builds on the complementarity between the two instruments on board. The WFM-IS is composed by 12 coded mask cameras equipped with Position Sensitive Detectors (visible in Fig.2 - left) (PSDs) distributed two by two around the hexagonal spacecraft envelope. Each pair of PSDs in the same hexagon side is co-aligned and directed towards the same direction which is radially tilted outwards of 15 degrees with respect to the satellite axis. Each PSD has a size

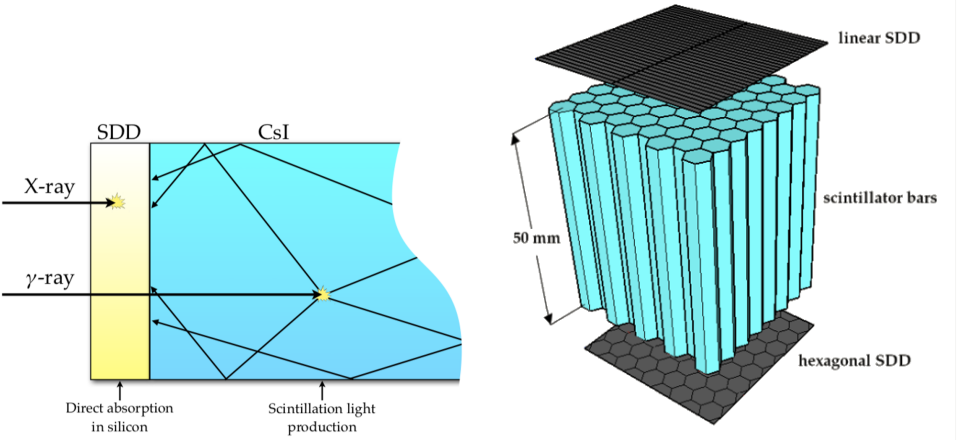

Fig. 3. Left: working principle of the WFM-IS. An hexagonal scintillator bar (cyan) is coupled at both ends (only one end is visible in the picture) with an SDD (yellow). The low energy radiation (< 30 keV) is directly absorbed in the SDD while higher energy photons pass through the SDD and interact in the scintillator bar. The scintillation light, which is produced at some distance from the surface of the scintillator bar and is reflected by the lateral surfaces, is collected by the two SDDs. The comparison between the two signals allows for the determination of the depth of interaction. Right: disposition of the scintillator bars (cyan) and of the top and bottom SDDs (grey). The top SDD is equipped with an array of linear anodes therefore the charge collected provides information only in one direction. In the bottom SDD the anodic structure has a hexagonal shape in order to fully exploit this geometry which minimizes the directional bias for polarimetric measurements, if compared with a detector with square (cubic) pixelization (voxelization).

of 43×42 cm^2 and is made of ~ 6500 scintillator bars with hexagonal cross section (5 mm between flat sides) and 50 mm long. Both ends of the scintillator bars are optically coupled with two Silicon Drift Detectors (SDDs) 400 μm thick. The instrument is based on the same detection principle of the X and Gamma-ray Imager and Spectrometer (XGIS) on board the THESEUS mission[6] which was proposed as 5^{th} medium-class mission for the ESA Cosmic Vision Programme (M5).

The detection principle (see Fig. 3) is based on a different interaction of the radiation with the system, depending on the energy of the interacting photons. Low energy photons (< 30 keV) are directly absorbed in the SDD while photons with higher energy pass through the SDD and interact in the scintillator bar. The scintillation light, which is produced at some distance from the ends of the scintillator bars, is reflected by the lateral surfaces which are properly polished and wrapped in order to reflect as much as possible the light produced, and it is collected by the two SDDs optically coupled at both ends of the bar. For high energy photons (>30 keV) the detector is position sensitive with a 3-D resolution given that the position of interaction of the gamma-ray photon along the bar can be reconstructed by comparing the signal collected from the two opposed SDDs. The top SDDs (those facing the sky) have the dual purpose of directly detecting the low energy photons (below few tens of keV) and of collecting the scintillation light emitted

by the scintillator bar when photons with higher energy pass through them. They have a linear anodic structure therefore are sensitive only to one direction (X or Y) with spatial resolution of 1.25 mm. Given that each pair of PSDs placed at the same side of the spacecraft have perpendicular anodes, they behave like a 2-D detector. Instead, the bottom SDD has hexagonal shape and it is used to get the 3-D position sensitivity. In this way we can minimize the background through the Compton kinematics reconstruction of the trajectory of the photons and exploit the polarimetric capability of the instrument. Different scintillator materials as Cesium Iodide (CsI(Tl)), Gadolinium Aluminium Gallium Garnet (GAGG), Lutetium Yttrium Orthosilicate (LYSO(Ce)) are under investigation in order to find the optimal properties to fit the instrument requirements. Each PSD is surmounted by a double scale[7] square coded mask with side of 80 cm at a distance of 70 cm from the detector plane (see Fig. 2 - right). The double scale enables imaging with Point Source Location Accuracy (PSLA) of 1 arcmin for a 7σ signal for photons with energy $<$ 30 keV and PSLA of 5 arcmin for photons in the energy range 30 - 150 keV. In Fig. 4 (left) the PSLA as a function of the significance of the observation for different configurations of the WFM-IS is reported, compared with required PSLA of 1 arcminute. In Fig. 4 (right) the integrated sensitivity of the overall WFM-IS is reported as a function of the integration time, divided in three relevant pass-bands according to the different detection principle employed (2 - 10 keV: direct detection in the SDDs, 30 - 150 keV: interaction with the scintillator bars, 150 keV - 10 MeV: uncollimated interaction in the scintillator bar). Above 150 keV the coded mask is transparent to radiation and an effective imaging capability can be enabled through two features: 1. by exploiting the Compton kinematics for the photon direction reconstruction and 2. by taking advantage of the different measured photon intensity from the 6 blocks which are - in general - differently oriented with respect to the direction of the observed event, except for perfectly on-axis sources. With these configuration the instrument can provide a FoV of $\sim$2 sr with an angular resolution of a few arcmin and an unprecedented energy pass-band of 2 keV - 20 MeV which has never been achieved so far with a single device.

The second instrument is a 20 m long focal length Laue lens based on bent crystals made with Germanium and Silicon. The crystals are distributed in 43 concentric rings and, according to the spherical geometry and to the Bragg law, the lower energies are reflected from outer rings while inner rings are responsible for focusing the higher energies. The size of the crystals have been chosen to be 30×10 mm^2, the longer dimension being the focusing direction. In the other direction, no concentration is expected due to the cylindrical curvature of the tiles. The cross section of the tiles has been chosen in order to tile the overall geometric area with a moderate number of crystals ($\sim$19500) by minimizing the amount of uncovered area (the optics filling factor results above 85%). Depending on the energy to be diffracted the crystal thickness is optimized in order to maximize the diffraction efficiency. For both materials the 111 planes are assumed in order to exploit the

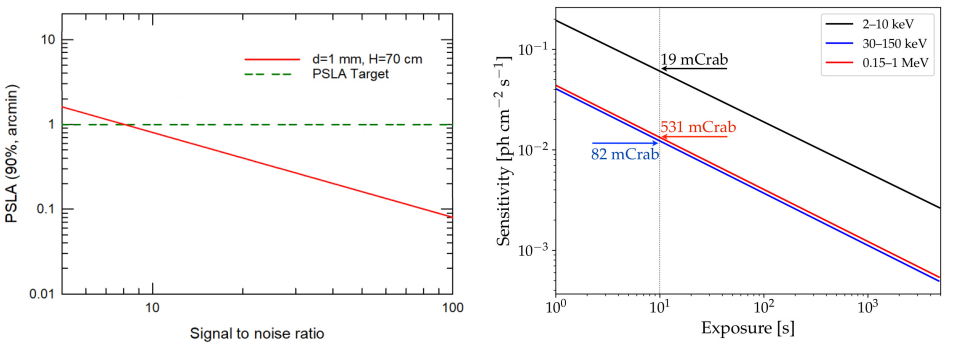

Fig. 4. Left: Point Source Location Accuracy (PSLA) for the WFM-IS as a function of the signal to noise ratio. The parameter d is the distance between the anodes of the top SDDs. The requird PSLA is also shown (green dashed line) Right: Integrated continuum sensitivity expressed in photons/cm^2/s as a function of the exposure time for the three significant energy pass-bands acquired for direct absorption in the SDDs (black curve, 2 - 10 keV), through the scintillation bars (30 - 150 keV, blue curve) and as a Compton detector with no coded mask (150 keV - 1 MeV, red curve).

so called secondary curvature of the diffraction planes induced in crystals for some crystallographic orientation (including the 111) allowing to achieve a throughput which overcomes the limitation of the 50% of the incident beam, which is the limit of mosaic and flat perfect crystals.

Orders of diffraction higher than the fundamental are being considered in the simulations in order to maximize the effective area, particularly in the energy range 500 - 520 keV (at the expenses of the effective area at lower energies) in order to increase the sensitivity at the energy of interest for the detection of the weak e^+/e^- annihilation line from the Galactic center (see Sect. 3 for further details). At 20 m from the optics is placed the focal plane detector which is kept at the correct position with a deployable mast. The detector is made with 4 layers of Cadmium Zinc Telluride (CZT) with cross section 80 $\times$ 80 mm^2 each with a thickness of 20 mm. The detector has a 3-D spatial resolution of about 300 μm in all directions. This is achievable with a proper disposition of the anodes on the top and bottom of each CZT layer. Thanks to the overall detector thickness its detection efficiency is greater than 80% at 600 keV with energy resolution of 1% at 511 keV.

The NFT continuum sensitivity which has been derived at Low Earth Orbit (LEO) by comparison with the background measured by the Spectrometer on-board INTEGRAL SPI[8] is reported in Fig. 6 (top). The curve has been estimated for an integration time of 10^5 s and at 3σ confidence level. For comparison, in the plot has been reported a number of past and present experiments exploiting the direct view principle (equipped with coded masks or collimators) or using focusing telescopes. The energy band in which it is estimated is $\Delta E = E/2$, except in the band from 50 keV to 62.5 keV, in which the energy band linearly increases from $\Delta E = E/4$ to $\Delta E = E/2$, due to the absence of crystals diffracting energies

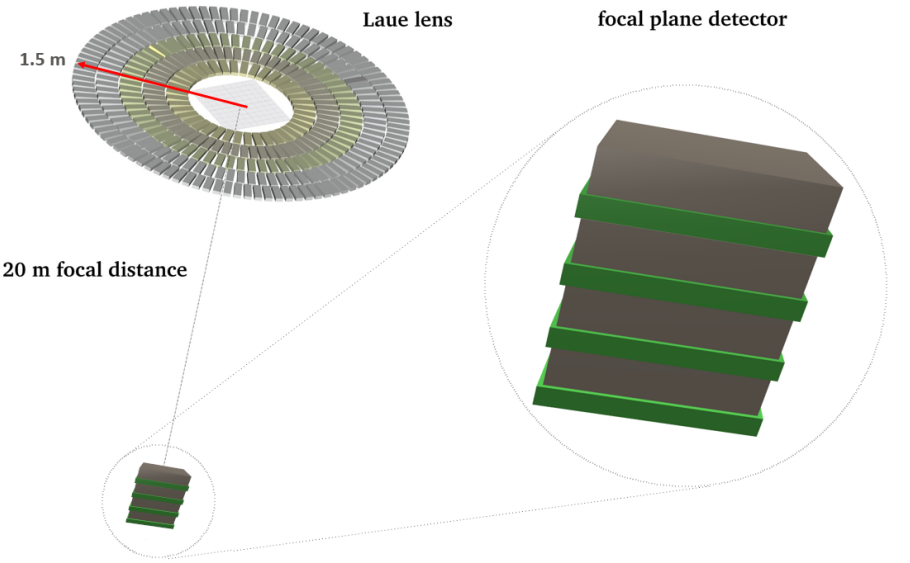

Fig. 5. Left: The optics of the NFT composed by 43 rings of crystal tiles made with Silicon and Germanium. The optics has a radius of 1.5 m for a total geometric area of about 7 m^2. At 20 m from the Laue lens is placed the focal plane detector. Right: a Geant4 drawing of the main components of the focal plane detector which is made of 4 layers of a solid state Cadmium Zinc Telluride (CZT, dark grey) with 3-D spatial resolution, spectral and polarimetric capabilities.

below 50 keV. Uncertainties in the realization of the optics have been also taken into account. The curvature radius of the crystals have been considered within 5% of the nominal radius and the mounting accuracy of about 10 arcseconds with respect to the nominal positioning. The presence of such deviations from the nominal lens realization requirements have effects on the size of the PSF and, ultimately, on the focusing power of the Laue lens. This unprecedented sensitivity is achieved thanks to the use of bent crystals with optimized thickness. Figure 6 (bottom) shows the sensitivity at measuring the flux of emission lines, at 3σ confidence level and for 10^5 s integration time. An intrinsic FWHM of 2 keV has been considered for the lines (e.g. see [9] for the 158 keV line from SN2014J). The narrow line sensitivity is about 1 order of magnitude better than SPI on board INTEGRAL at 511 keV. These values of sensitivities are mainly due to the use of bent crystals, to the transmission geometry and to the focal length that allows for an unprecedented large collecting area.

Laue optics have the great advantage of drastically reducing the instrumental background as the photons are mainly collected into an area of a few mm^2. The drawback is that, as far as the source moves out of the focal axis, the diffracted image spreads over a larger area generating ring-shaped images for coma aberrations. Through ray-tracing and Monte Carlo simulations it has been estimated that,

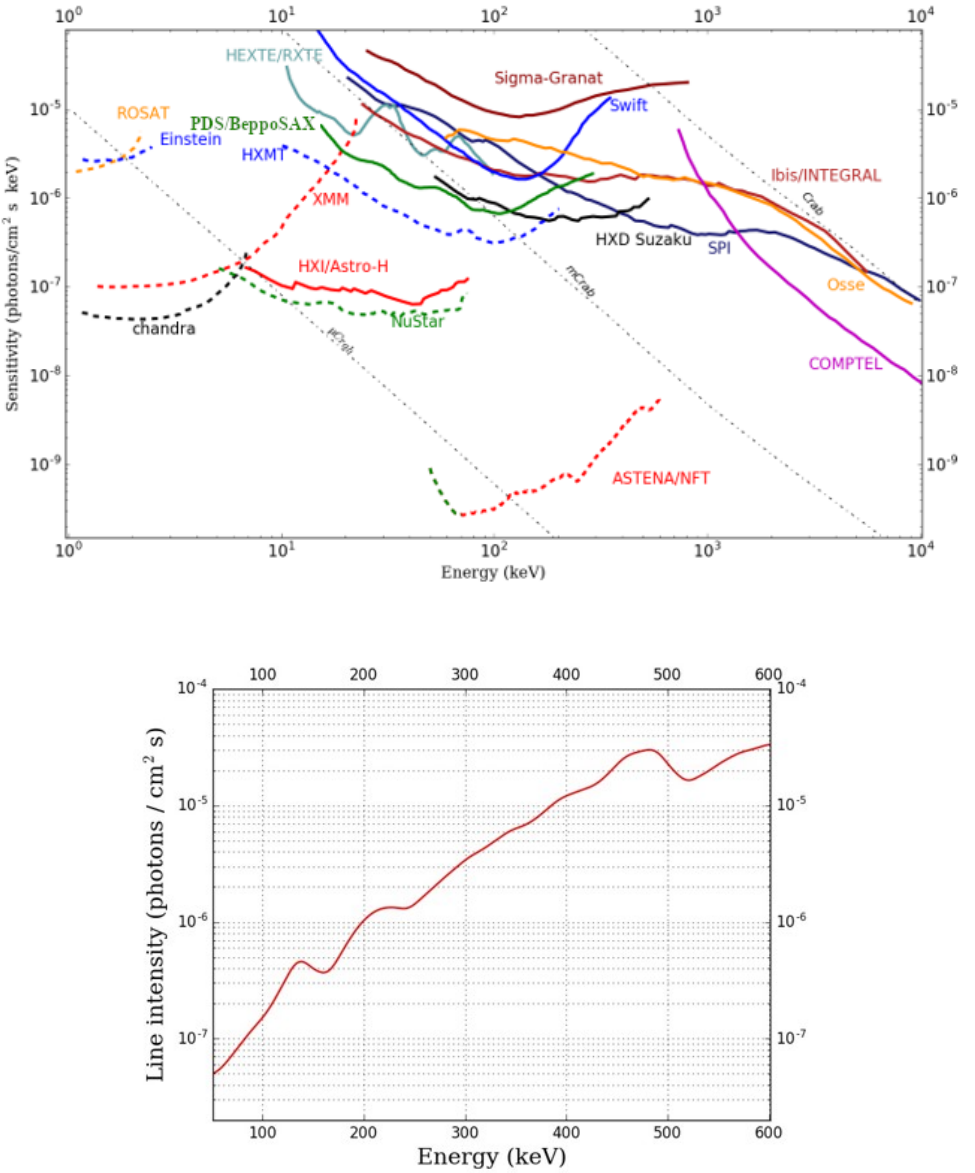

Fig. 6. Top: NFT continuum sensitivity at 3σ confidence level and in 10^5 s of observation time, with $\Delta E = E/2$, except in the band 50 to 62.5 keV, where ΔE linearly increases from $\Delta E = E/4$ to $\Delta E = E/2$, compared with the sensitivity at the same significance and with the same integration time of other missions or experiments (dashed lines represent other focusing experiment, continuum curves correspond to direct view instruments). Bottom: Expected line sensitivity for the NFT, calculated for an integration time of 10^5 s, at 3σ confidence level.

with the defined optics dimension and crystal size, photons from off-axis sources (>4 arcmin) are scattered into a broad detection area.[10] This reduces the benefits of the focusing process. Therefore the FOV of the NFT has been fitted with the PSLA of the WFM-IS in order to exploit the sensitivity of the former for nearly on-axis sources with the excellent broad-band survey capabilities of the latter.

3. Key science with ASTENA

For some relevant scientific key subjects that can be tackled with the instruments on board ASTENA see [10, 11]. Here we summarize these subjects. As mentioned in Sect. 1 the main objectives of the ASTENA mission concept are mainly two. First, ASTENA intends to investigate the intriguing key questions related to the gamma-ray lines in astrophysics. Furthermore, the high sensitivity of the on board instruments joined with the large pass-band of the WFM-IS and their polarimetric capabilities would make ASTENA an ideal tool for shading light in the transient sky, providing also an important contributions to the multi-messenger synergy.

3.1. *The transient sky observed with ASTENA*

The discovery of the Gravitational Wave (GW) event GW170817[12] and its electromagnetic counterpart GRB170817A[13–16] marked the birth of the multi-messenger study of the transient sky. In the near future, this plural effort will solve fundamental astrophysics and cosmological questions. Furthermore, it will boost the discovery of sources of known and unknown classes of transients. Short GRBs represent the main class of transient which has been already confirmed to be associated with powerful GW events.

Polarization level in the range 30 - 80% of the prompt emission of the GRBs has been claimed for a few dozens events (a summary of the properties of the events can be found in [17, 18]) but, due to the limited statistical significance of the results, their confirmation is not definitive. These uncertainties are mainly due to the lack of sensitivity of the instruments used as gamma-ray polarimeters. A significant detection could probe the geometry of the magnetic field and its intensity which are precious information for shedding light into the jet composition and dissipation mechanism. Thanks to its polarimetric capabilities, along with a large detection area and broad pass-band, the WFM-IS would be the ideal instrument to measure the degree of polarization of the prompt emission, to perform a detailed time-resolved study and to evaluate the dependence of the polarization degree with energy.

Instruments capable of measuring the electromagnetic counterpart of GW events have a crucial importance for different reasons. Firstly, they can independently confirm the astrophysical nature of a GW trigger, particularly for the faintest events. Furthermore, since present interferometers have large uncertainties in the sky localization, a high sensitive wide FoV instrument like the WFM-IS could provide the localization of the order of 1 arcmin with the possibility of performing followup

observation with a soft gamma-ray telescope with an unprecedented sensitivity and angular resolution as the NFT.

It must be mentioned that with the launch of the Laser Interferometer Space Antenna (LISA) a plethora of GW events from stellar mass BH binaries will be detected in the mHz regime with a sky localization of the order of 1 deg^2. Such detections will work as alert for the observation of the same events at higher frequencies weeks/months later (with an accuracy of the order of tens of seconds) from ground interferometers. Thanks to the large FoV and to the PSLA of the WFM-IS will be possible to point in advance the instrument for the detection of the prompt hard X-ray counterpart of the event as well as the detection of the delayed hard X-ray emission through the NFT.

After the discovery of the GRB afterglow, till now this emission has been observed almost in all energy bands from IR to the soft X-ray regime up to ~ 10 keV. Afterglow detection in the 0.1–10 GeV, in the sub-TeV (100–440 GeV) and in the TeV energy regions have been reported.[19,20] One of the most important open issues that have still to be settled is the afterglow emission in the sub-MeV/MeV region which is almost completely undetected except for some events detected above few tens of keV[21–23] This is mainly due to the low flux emitted in this energy band, joined with the lack of sensitivity for the present instrumentation. From the prompt emission detected with the WFM-IS and though a fast repointing it would be possible, thanks to the sensitivity of the NFT, to measure the hard x-ray afterglow as well as its polarization level.

3.2. *Nuclear astrophysics with ASTENA*

In spite of its importance for understanding the inner regions of the astrophysical sources emitting hard X and mainly gamma-rays, nuclear astrophysics is still a theoretical field and almost experimentally unexplored, mainly due to observational limits. The reason is that present instrumentation in the hard-X and gamma-ray regime has absent or crude imaging capability and low sensitivity, compared with instruments in other wavelengths. One of the most relevant open issues in astrophysics is the origin of the 511 keV positron annihilation line observed from the Galactic Center (GC). Discovered in the seventies[24] neither the origin of the gamma emission, nor the responsible for the positron production have been found. The 511 keV annihilation line still represents a puzzle mainly due to the limitation of both sensitivity and angular resolution of current instruments operative in the 0.5 MeV region. To date, the best mapping of the line was obtained through SPI on-board INTEGRAL.[25] A variety of potential astrophysical sources responsible of the 511 keV signal and/or of the production of the positrons have been proposed, including type Ia supernovae,[26] GRBs,[27] microquasars,[28] low-mass X-ray binaries,[29] and neutron star mergers.[30] The high number of X–ray sources in the GC suggests the possibility that the 511 keV line is due to the emission of a number of discrete - unresolved - sources. The detection of a transient 0.5 MeV emission from V404 Cygni[31] is in

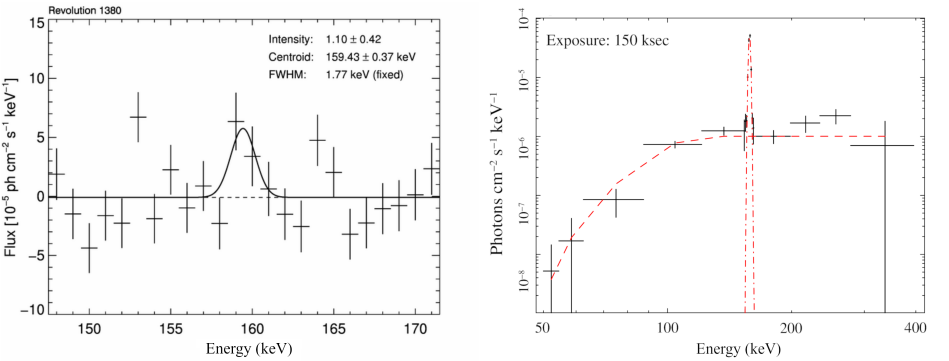

Fig. 7. Left: the 158 keV line due to the ^{56}Ni decay as observed from SN2014J as with the SPI on board INTEGRAL 3 weeks after the explosion. Reprinted from [9]. Right: the same line as observed with the NFT onboard ASTENA with 150 ks integration time. The simulated data (black points) consists of a continuum modeled with an absorbed power-law (red dashed line) with spectral index $\alpha = 0$ normalization 10^{-6} ph/cm^2/s @ 1 keV plus a Gaussian (red dot-dashed line) centered at 158 keV with σ=0.75 keV and normalization 1.1×10^{-4} ph/cm^2/s.

favour of this hypothesis. It is also believed that the 511 keV observed map would only represent the annihilation sites and not the positron sources. The propagation of the positrons away from the source could be the cause of a general broadening which originates the diffuse 511 keV emission. No point sources of annihilation radiation have yet been detected in the GC. Nevertheless, the angular resolution of INTEGRAL/SPI does not provide any definitive information about structure in the emission, even with several years of integrated data.[32] Under these considerations it is clear that observations of the GC with much higher angular resolution than that achievable with SPI aboard INTEGRAL together with high sensitive instruments are required in order to distinguish and localize - if any - discrete source of annihilation radiation.

Another topic under study that is worth to be mentioned is related to the nucleosynthesis of heavy elements in Type-Ia supernovae (SNe-Ia). Gamma-rays escaping the ejecta of SN-Ia can be used as tools for studying both the structure of the exploding star and the characteristics of the explosion. One of the key points is to estimate the amount of ^{56}Ni which is probably the most important physical parameter underlying the observed correlation of SNe-Ia luminosities with their light curves. The only direct way to estimate this amount is through the decay chain $^{56}\text{Ni} \rightarrow {}^{56}\text{Co} \rightarrow {}^{56}\text{Fe}$. The decay produces gamma-rays that ultimately power the optical light curve of the SN-Ia. Most models predict that the ejected material is not transparent to gamma-rays at least for tens of days since the explosion. As the ejecta proceeds, it becomes gradually more transparent to gamma-rays. Contrarily to the expectations, only two weeks after SN2014J through SPI/INTEGRAL observations, the characteristic gamma-ray lines 158 keV and 812 keV from the ^{56}Ni decay have been detected [9] and later confirmed at 5σ confidence level also with

ISGRI/INTEGRAL.[33] The early observations of gamma-rays from ^{56}Ni support the hypotesis of the presence of this element at the star surface. The intensity of the gamma-ray spectra mainly depends on the mass and distribution of the nickel mass. High sensitivity measurements focused at particular narrow lines would shed light on the SNe-Ia explosion mechanism and, ultimately to the correct distribution and mass of ^{56}Ni.

As an example of performances with ASTENA, in Fig. 7 we show the 158 keV line detected with SPI/INTEGRAL from SN2014J[9] for an exposure time of 150 ks. The estimated line intensity of $(1.1\pm 0.4) \times 10^{-4}$ ph/cm^2/s corresponds to a detection confidence level of 2.5σ. For comparison, with the same integration time, a spectrum consisting of a Gaussian profile (centroid energy 158 keV, $\sigma = 0.75$ keV) superposed to a continuum described by a power-law with spectra slope α=0 and normalization 10^{-6} ph/cm^2/s @ 1 keV has been simulated in order to estimate how it could be observed with the NFT aboard ASTENA. The same significance achieved by SPI in 150 ks is obtained in $\sim$1 ks.

4. Conclusions

Future missions for hard X-ray astrophysics require higher sensitivity than current instrumentation and capability of observing the sky in a broad energy pass-band. Such features will be crucial for solving some of the most important open issues. In addition, hard-X and soft gamma-ray polarimetry, which are still in their infancy, will play a crucial role in combination with spectroscopy, timing and imaging, providing information about the degree and the direction of polarization of the incident radiation. Particularly in hard X-rays, whose emission comes directly from the central engine of the sources, polarimetry is a powerful tool for investigating the magnetic field and the distribution of matter around astrophysical objects. Moreover, today hard X-/gamma-ray astrophysics suffers from the absence of devices that allow the radiation to be focused, the only method through which it is possible to increase the signal to noise of the observations and to suppress the instrumental background.

The ASTENA mission concept includes two complementary instruments through which it is possible to carry out both polarimetry and imaging in the hard X-ray regime. The WFM-IS is an array of 12 monitors that can effectively work in an unprecedented energy pass-band for a single instrument (2 keV - 20 MeV) thanks to the coupling of SDDs a and scintillator bars. Thanks to the adoption of a double scale coded mask, the instrument enables localization accuracy of about 1 arcmin and 5 arcmin in the energy pass-bands $<$ 30 keV and 30 - 150 keV, respectively. With this location accuracy, the WFM-IS is in complete synergy with the second instrument on board, the NFT: for the first time a focusing optics based on a Laue lens will be operative in a broad pass-band and with a FoV of a 4-5 arcminutes and an angular resolution of a few tens of arcseconds. Thanks to its focusing capability it provides an outstanding sensitivity for detecting source polarization[34] and both for

the continuum and for nuclear lines. The unprecedented broad pass band and the large FoV of the WFM-IS will allow to make surveys and to detect faint transient sources, including GRBs. The NFT, with its deep sensitivity for nearly on-axis sources, will be the ideal tool for followup observations of detected transient events.

In this work we have presented the ASTENA mission concept and details on both instruments aboard. We have described some key science issues that can be tackled with ASTENA as a stand-alone experiment and in synergy with other experiments, including its contribution to the multi-messenger astrophysics. We expect that a mission like ASTENA will be a breakthrough in general astrophysics and in particular for answering the questions that are still central in high energy astrophysics.

The measurement of the polarization of the high-energy photons from cosmic sources has now become a key observational parameter for understanding the emission mechanisms and the geometry of the active regions involved. Therefore, a mandatory requirement for new instrumentation in this energy regime will provide high sensitivity for polarimetric measurements associated with spectroscopy and imaging.

In this perspective, the Advanced Surveyor of Transient Events and Nuclear Astrophysics (ASTENA) mission, which includes two main instruments: the Wide field monitor (WFM-IS), with a large effective area and a wide energy passband (2 keV – 20 MeV); and the Narrow Field Telescope (NFT), with a broad energy passband (50–600 keV) with focusing capabilities based on the use of an advanced Laue lens; will both provide high sensitivity for polarimetric measurements. Furthermore, both instruments will include spectometers with a good 3D spatial resolution allowing to perform 3D Compton polarimetry, increasing the possibilities to optimize the event selection. Herein, we report on the results of a Monte Carlo study devoted to optimize the configuration of both instruments, in particular, the modulation factor (Q), the events detection efficiency (Eff) and the Minimum Detectable Polarization (MDP).

Keywords: Polarimetry, Gamma-ray detectors, Space instrumentation, Compton scattering.

1. Introduction

Polarimetry of high-energy sources is a key observational parameter for a better understanding of the emission mechanisms and geometry of a wide number of cosmic objects and events such as GRBs, pulsars, binary black holes and active galactic nuclei, whose emissions are expected to be polarized. The field of hard

X-ray polarimetry has been quite active in the last two decades: missions such as INTEGRAL, AstroSat and POLAR have provided some important scientific inputs in understanding emission mechanism and geometry in X-ray pulsars,[1–3] magnetic field structure in Pulsar Wind Nebula (PWN),[1,4] disk-jet interplay in black hole X-ray binaries (XRBs)[5,6] and hard X-ray emission mechanism in GRB prompt emission.[7–9] Though these results are marred with large uncertainties and a firm conclusion is not possible, most of these findings are extremely interesting as they pose new challenges to the existing theories. One interesting and common feature in all these measurements is a systematic increase in polarization within the hard X-ray band which makes this energy regime extremely promising for polarimetry experiments.[10]

As a part of the European project AHEAD (integrated Activities in the High Energy Astrophysics Domain), a new concept of high energy mission named ASTENA (Advanced Surveyor of Transient Events and Nuclear Astrophysics) has been proposed and accepted for feasibility and performance study.[11] In the current AHEAD 2020 project, which is a continuation of AHEAD, we deepen the feasibility study of ASTENA and increase our knowledge on the potential performances of the instruments on board concerning spectral, imaging and, particularly in this context, polarization capabilities. In this work we present the results of a study that aims to reliably and realistically evaluate the performance in terms of polarimetry that can be achieved with the ASTENA and to optimize the design of the detection units to achieve this aim taking into account the requirements.

2. ASTENA

The ASTENA configuration is described in,[12] and it is shown in Fig. 1. Its main properties are summarized in Table 1. The instrumentation on board consists of a Wide Field Monitor–Imaging Spectrometer (WFM-IS) with a 2 keV–20 MeV passband, and a Narrow Field Telescope (NFT) with a 50–600 keV passband.

Table 1. Summary of the main properties of the WFM-IS and of the NFT on board ASTENA.

	WFM-IS	NFT
Energy pass-band	2 keV – 20 MeV	50 – 600 keV
Total useful area[a]	$\sim$ 5800 cm^2 ($<$ 30 keV) $\sim$ 6700 cm^2 (30–150 keV) $\sim$ 13800 cm^2 (>200 keV)	7 m^2 (projected)
Field of View	2 sr	4 arcmin
Angular resolution	6 arcmin	$\sim$ 30 arcsec HPD
Point source localization accuracy	1 arcmin	$<$ 10 arcsec
3σ, **Continuum Sensitivity** (ph/cm^2 s keV)	1×10^{-4} (10 s, 30–150 keV)	1.2×10^{-9} (10^5 s, 225–375 keV)
3σ, 10^5 s **Line sensitivity** (ph/cm^2 s)	-	5×10^{-7} (178 keV)

Note: [a]Total geometric area through the mask or collimator.

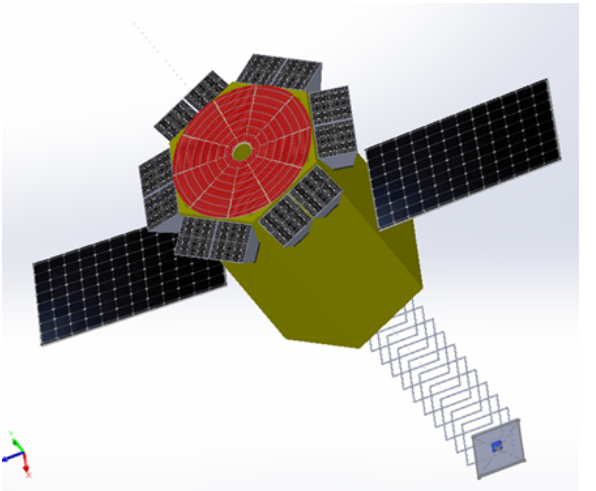

Fig. 1. The ASTENA satellite in inflight configuration. The WFM/S modules surround the NFT Laue lens (front), while its focal plane is positioned 20 m apart by a booming structure (back).

The NFT is a Laue lens focusing telescope with a 3 m diameter and 20 m focal length, composed by a large number of crystal tiles in transmission configuration, that are disposed in such a way that they concentrate the incident radiation onto a common focal spot.[13] The lens proposed for the NFT is made of ∼19500 bent crystal tiles of Si(111) and Ge(111), with 40 m curvature radius (within 5% uncertainty). The crystal tiles have a 30×10 mm^2 cross section, and an optimized thickness vs. energy for maximizing the diffraction efficiency, with the condition of a maximum thickness of 5 mm. The crystals are disposed on 43 rings, with an outermost ring radius of 149 cm and an innermost of 18 cm, ensuring an energy passband of 50 keV (outermost rings) to 600 keV (innermost rings). Current Monte Carlo simulations, ray-trace analyses and laboratory experiments evaluated that an angular resolution of 0.5 arcmin can be achieved, with a useful FOV of approximately 4 arcmin.[14]

Concerning the NFT focal plane detector, the adopted configuration consists of 4 layers of drift strip detectors of CdZnTe,[15] each layer with a cross section a 80×80 mm^2 and a thickness of 20 mm. This configuration will ensure a detection efficiency higher than 80% in the entire energy band of the NFT, a spectroscopy response of 1% @ 511 keV and fine spatial resolution (0.2–0.3 mm) in three dimensions,[16] allowing the correct sampling of the Point Spread Function (PSF) of the lens, that is of the order of a few mm^2. Thanks to the unprecedented sensitivity that can be achieved with the Laue lens focusing technique and the high segmentation level the focal plane detector, NFT is expected to provide fine polarization measurements.

The WFM-IS consists of an array of 12 units, two units on each side of the hexagon surrounding the NFT, accommodated as shown in Fig. 1. All the units are

offset by 15 deg with respect to the axis of the NFT. Each WFM-IS unit consists of a 40×40 array of detection elements, each made of a scintillator bar (CsI(TI) or similar) 5 cm long, with an hexagonal cross section of about 75 mm^2, viewed by two Silicon Drift Detectors (SDD) 0.4 mm thick, one on the top (side of entrance of the celestial photons) and other on the bottom. The functioning principle of this detector is similar to that adopted for the X-Gamma-ray Imaging Spectrometer (XGIS) aboard the THESEUS mission concept.[17] It has the great advantage of a very broad passband (2 keV–20 MeV), a 3-D position sensitivity to energy losses in the scintillator bars and a very low intrinsic background. The hexagonal cross section of the bars, which allows us to obtain a low geometric systematic effect in the polarization measurements, associated with the 3D position sensitivity of the detector makes the WFM-IS suitable for fine polarization measurements.[11]

3. Compton Polarimetry with ASTENA

In the hard X- and soft γ-rays regime the measurement of the polarization status of a photon beam rely on the Compton scattering mechanism. The detectors on-board ASTENA provide the segmentation needed to offer an efficient method to measure the linear polarisation of incoming photons using Compton scattering because, with a coincidence event logic, each element/pixel can act at the same time both as a scattering element and as a detection unit allowing to record the pairs of events that provide polarimetric information: one is the Compton scattering of the incoming photon, the other is the interaction by Compton or photoelectric effect of the secondary photon.[10]

The cross-section of a hard X-ray photon to interact with a free electron is given by the Compton scattering cross-section described by the Klein–Nishina equation[18]:

$$\frac{d\sigma}{d\Omega} = \frac{r_0^2 \varepsilon^2}{2} \left(\frac{1}{\varepsilon} + \varepsilon - 2 \sin^2 \theta \cos^2 \varphi \right) \tag{1}$$

where r_0^2 is the classic electron radius, $\varepsilon = E'/E$ the ratio between the energy of the scattered photon and the energy of the incoming photon, θ is the scattering angle of the scattered photon measured from the direction of the incident photon, and φ is the azimuth scattering angle with respect to the electric vector of the incident photon. On a segmented detector the distribution of the azimuthal angle measured on a large sample of data has a sinusoidal behavior with period π

$$N(\phi) = a_0(1 + a_1 \cos(2(\phi - a_2 + \pi/2))) \tag{2}$$

where a_0 is the normalization constant, $Q = a_1$ the modulation factor, and $P = a_2$ the polarization angle which are obtained from a fit to the data. This distribution is the called "modulation curve", which is built dividing the scattering map on a fixed number of angular sectors, covering 360°, and integrating the counts inside each

angular sector. The aperture of the angular sectors should be chosen taking into account the discretization level of the detector (i.e., the pixel dimensions) and the counts statistics. Because of the segmented nature of the detector, the integration of count inside a defined angular sector should take into account effects due to pixels that lie across their borders. Methods to account for these pixels are, for example, that of distributing uniformly the pixel counts proportionally to the area of the pixel intercepted by two adjacent angular sectors. For the analyses performed the number of bins of the azimuthal distribution was optimized for each instrument since it affects the shape of the modulation curve.

In the characterization of a polarimeter it is important to describe its response not only to polarized, but also to unpolarized signals. For a perfectly uniform and symmetric instrument the modulation curve from a 0% polarized signal should be totally flat. However, the detector geometry introduces an asymmetry that is important to correct the signal from this component. We correct the measured modulation curve from the instrument response to a unpolarized signal by applying the following expression for each angle bin:

$$N_{corr}(\phi) = \frac{N_p(\phi)}{N_{np}(\phi)} N_{np}^{max} \tag{3}$$

where $N_{corr}(\phi)$ is the corrected azimuthal distribution, $N_p(\phi)$ is the polarized azimuthal distribution, $N_{np}(\phi)$ the non polarized modulation azimuthal distribution, and N_{np}^{max} the maximum of the non polarized azimuthal distribution. In practice, the systematic uncertainty in the polarization measurement will be estimated from the results of an extensive on-ground calibration campaign of the instruments, using both polarized and unpolarized monochromatic beams of gamma rays.

The minimum detectable polarization (MDP) of an instrument for a given celestial source type is an essential parameter to estimate its polarimetric potential. For a space polarimeter in a background dominated environment, the MDP with a 99% confidence level, is given by[19]:

$$MDP = \frac{4.29}{A.\epsilon.S_F.Q_{100}} \sqrt{\frac{A.\epsilon.S_f + B}{T}} \tag{4}$$

where, A is the effective area, ϵ is the events' efficiency, S_F is the source flux over the selected energy band (photons cm^{-2} s^{-1}), B is the background noise count rate (counts/s), T is the observation time (s) and Q_{100} is the polarimetric modulation factor for a 100% polarized source.

High polarimetric performance for hard X/soft γ-rays can be achieved fulfilling the following requirements: high scattering efficiency, fine spatial resolution, and fine spectroscopy. These characteristics allow a large flexibility in scattered events selection, and therefore several event filter can be implemented to optimize the modulation factor and the event efficiency, and consequently improve the MDP.

4. Polarimetric Analyses for a Monochromatic Source

4.1. *NFT*

In order to fulfil the requirements on the ASTENA NFT, and following the knowhow acquired by both experiments on CdTe/CZT detectors used as scattering polarimeter and development on 3D CZT spectrometers,[20] a simple model of the NFT focal plane has been implemented using MEGALib tools.[21] Using the MEGAlib/Geomega package, we implement a numerical model made of a stack of 4 thick layers of CZT separated by a layer (10 mm thick) of a PCB type mixture passive material, representative of the read-out front-end electronics board (Fig. 2). Each CZT layer is 20 mm thick and 80 mm × 80 mm wide. The CZT layers were divided in voxels with dimensions 0.25 x 0.25 x 0.25 mm^3 each. The spectroscopic response of the detector is simply modeled by a relationship derived from measurements on CZT drift strips spectrometers.[22] In all the performed simulation runs, we set the low energy threshold to 5 keV, that is a reasonable value at room temperature as demonstrated by the same experimental results.

The Laue lens configuration will impinge an almost monochromatic beam for each crystal ring on the detector, each one having a small inclination angle with respect to the axis of the lens, ranging from 0.4° (at the energy of 600 keV, corresponding to the inner radius) to 4.5° (at the energy of 50 keV, corresponding to the external radius). This will produce rings of photons with similar energy hitting the detector inside a PSF. We know from previous experiments that an off-axis beam introduce geometric effects on the detector that affect the modulation factor.[23] However, since the Laue lens presents a 180° symmetry, for each beam there will be a symmetric beam with opposite off-axis angle. This configuration will correct any possible systematic error due to the off-axis beam and the results will be similar as we impinge an on-axis beam on the detector. In fact, a systematic study was performed in order to validate this assumption. We evaluated the modulation factor by varying the number of pair of symmetric off-axis beams from 1 to 128, obtaining a distribution of values for the modulation factor with a standard deviation of 0.02 from the central value which is comparable with the error on the values of the modulation factor. To simulate a full Laue lens would require ∼20000 beams, each with its off-axis angle, however, by taking into account the aforementioned results, we decided to use instead a Gaussian cone shape beam, 20 m from the detector, which produce a Gaussian shape PSF with a FWHM of 0.15 cm on the top of the detector. This will simplify the simulation code and speed up the simulations without compromising the result.

To ensure the quality of the selected events we perform a check by Compton kinematics – by evaluating the energy of the two first interactions and the corresponding scattering angle we ensure that it corresponds to the expected values and the event can be selected as a "good event". This also can be done for multiple interactions, by using the energy of the first interaction, the sum of the following interactions

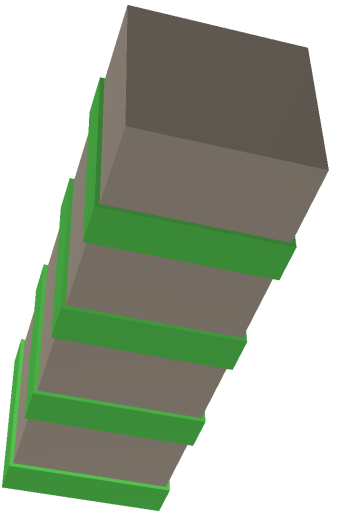

Fig. 2. Monte Carlo model of the the NFT focal plane. The gray volumes represent the segmented CZT spectrometer, while the green ones represent the readout electronics boards.

and the scattering angle from the first and second interaction. This method ensures that all the events selected are true Compton events and have polarimetric information on it. This method also removes the double events that occur in neighbour pixels. These type of events can introduce anomalies because the scattering angle is difficult to know. Since we consider the interaction in the center of pixel these types of events will be considered as a $\sim 90^{\circ}$ scattering event (high polarimetric information). However, if the interactions occur near the edges of the pixels the scattering angle can be $\sim 0^{\circ}$ (low polarimetric information).

Due to the focusing properties of the NFT we know that the first interaction is always inside the PSF. These allows a further correction since we only select the events which complies with this condition. This will reduce the background or any spurious events that occur in the detector.

After the selections, the scattering maps and modulation curves are drawn. To correct the systematic effects introduced by the detector geometry we also simulate an unpolarized source in the same conditions as the polarized source and we corrected the distributions with equation 3. As an example Fig. 3 presents the scattering maps obtained for a 300 keV unpolarized beam and for a 100% polarized beam with a polarization vector direction of 60°. By diving the scattering maps into 24 bins we achieved the azimuthal distributions presented in Fig. 3, below each scattering map. The corrected modulation curve is presented in Fig. 4. The corrected curve is then fitted with equation 2 to get the modulation factor and the polarization angle.

In Fig. 5 it is presented the modulation factor as function of the energy for the NFT focal plane for monochromatic beams ranging from 100 to 600 keV. These

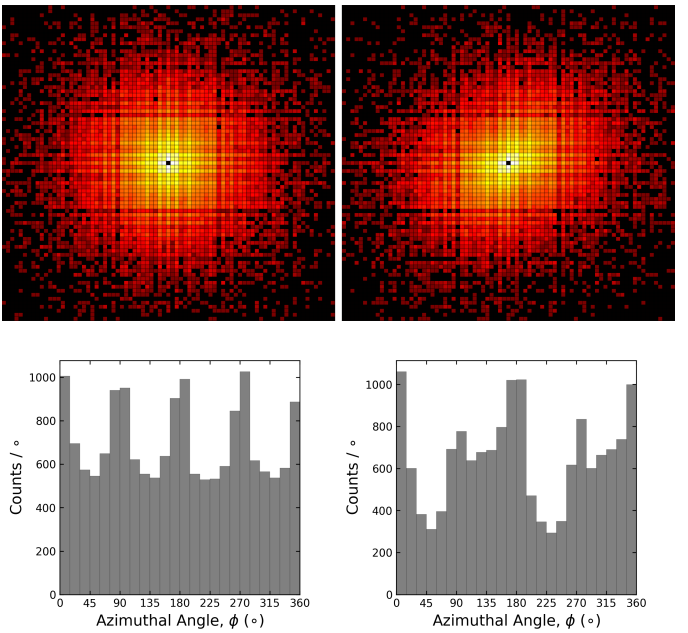

Fig. 3. Scattering maps and azimuthal distributions obtained for an unpolarized (left) and 100% polarized (right) beam. The beam energy is 300 keV and the polarization vector direction is 60° for the 100% polarized case.

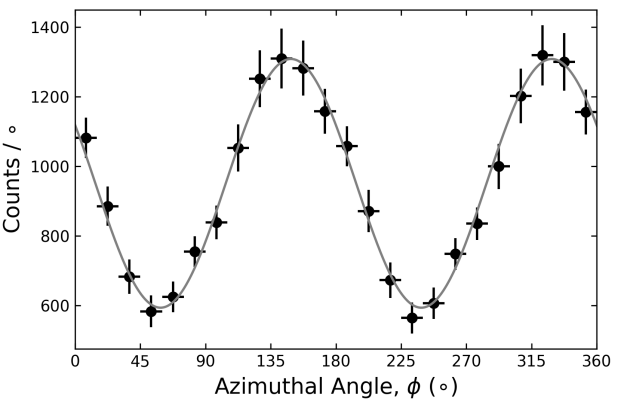

Fig. 4. Corrected modulation curve obtained when we apply the correction in Eq. (3) on the histograms of Fig. 3.

results showed that the NFT Focal Plane Detector (FPD) has potential to perform polarimetric analysis in the whole energy range presenting modulation factors >0.2. As expected, the best modulation factor is obtained at energies ∼300 keV.

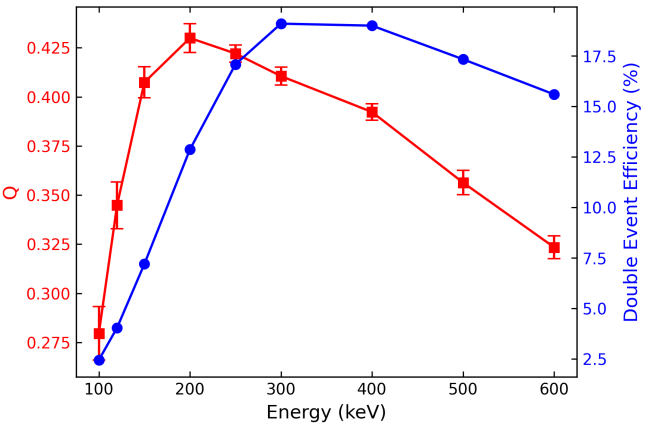

Fig. 5. NFT modulation factor and event efficiency as function of the energy.

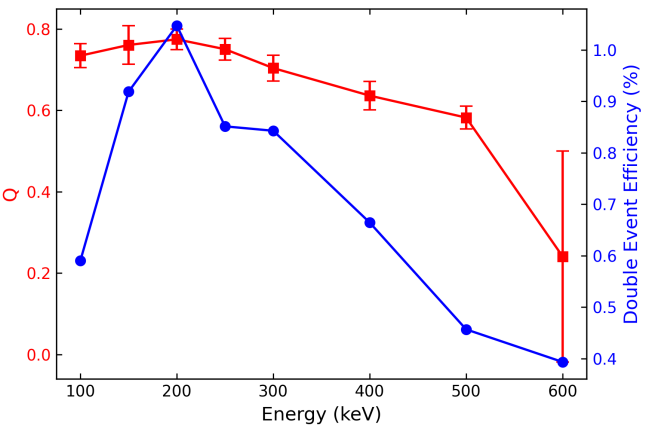

Fig. 6. NFT modulation factor and event efficiency as function of the energy for events with scattering angles of $\sim 90°$.

The percentage of selected events shows its maximum at $\sim$200 keV where the Compton cross section prevails over the other interactions in the CZT.

Due to the highly segmented detector we can also select events that maximize the modulation factor like events with scattering angles $\sim 90°$ (along the detector axis). By making a selection in the Z coordinates we ensure that all the events have $\sim 90°$. In Fig. 6 it is shown the modulation factor as a function of the energy taking account this selection. As can be seen, there is a big increase of the modulation factor when compared with the results without selection. The modulation factor reaches values near $\sim$0.8 for energies $\sim$200 keV. However the efficiency is very affected and reduced to values below $\sim$1%.

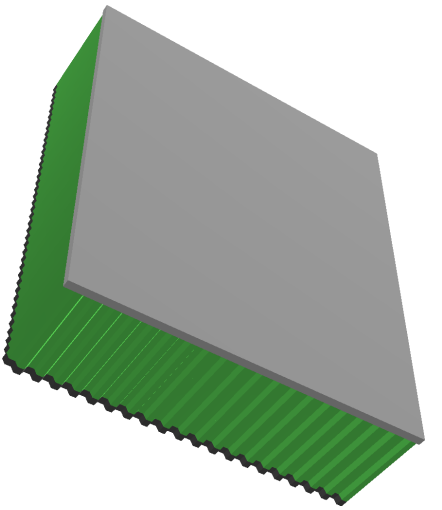

Fig. 7. A geometry sketch of the the WFM-IS unit. The green volume represent the CsI scintillators, while the gray ones represent the Si SDDs, light gray on top and dark gray on bottom.

4.2. *WFM-IS*

The Monte Carlo model of one WFM-IS unit is presented in Fig. 7. It consists of an hexagonal 40x40 array of CsI scintillators (for a total of 205 bars), with a distance between contiguous centres across hexagon flat sides of 5 mm, and a length of 50 mm. To mimic the depth resolution of the detector we segmented the bars in 10 segments of 5 mm each. On the top the detector has a linear SDD, 0.4 mm thick, and, on bottom an hexagonal single anode SDD, 0.4 mm thick, with a distance between hexagon flat sides of 5 mm. To construct the full WFM-IS we copied 12 units and placed along an hexagonal configuration, 2 units in each hexagon side, with a distance from the center (lens axis) of 1.5 m.

Since the WFM-IS is a wide field instrument, the beam used for the simulations was a far point source. For the WFM-IS we do not know were the beam undergoes the first interaction, all the scintillating bars will be scattering and absorbing elements, so we selected the events that comply the Compton kinematics and we corrected the signal data with the unpolarized data. In Fig. 8 the scattering maps are shown for a 500 keV unpolarized and 100% polarized source.

A systematic study was performed using monochromatic sources from 125 keV to 5 MeV. Fig. 9 shows the modulation factor and efficiency obtained for one WFM-IS unit and the full WFM-IS. As can be seen, for energies below 1 MeV the modulation factor shows values >0.2, however for energies above 1 MeV the modulation factor drops drastically becoming impossible to get polarization results. The reason for this is that for energies > 1 MeV both the theoretic value of the modulation factor and the efficiency of the Compton process drop significantly.[10] When comparing

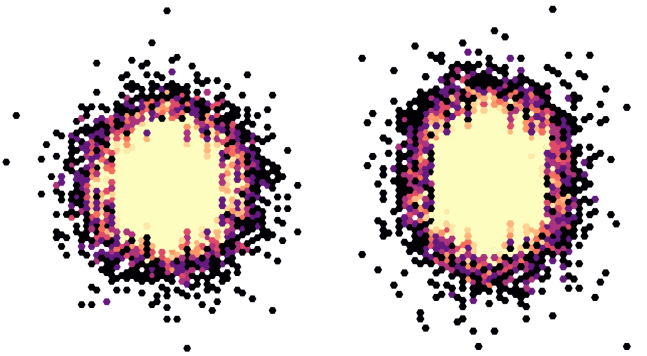

Fig. 8. Scattering maps obtained for a 500 keV unpolarized (left) and 100% polarized (right) beam with the WFM-IS unit. The polarization vector direction is 0° for the 100% polarized case.

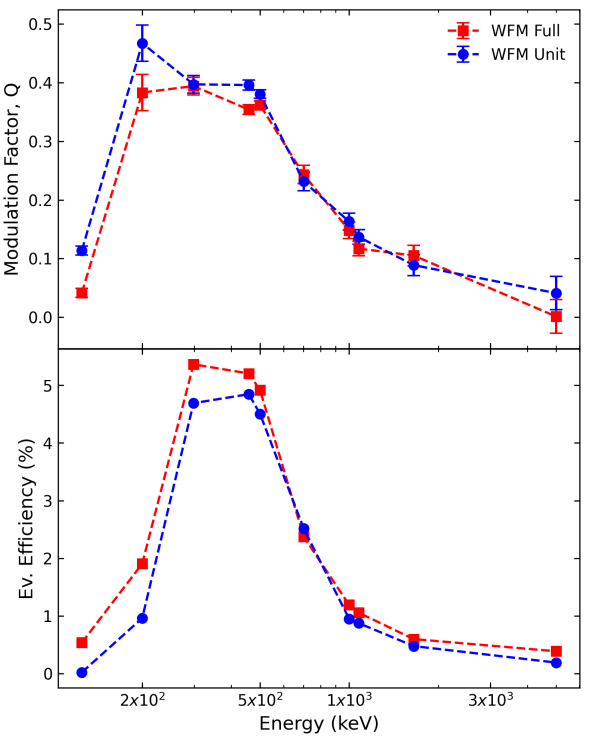

Fig. 9. Modulation factor (top) and event efficiency (bottom) as function of the energy for one WFM-IS unit and for the full WFM-IS.

the results for one WFM-IS unit and for the full WFM-IS the results of the modulation factor are similar, however the event efficiency increases when using the full WFM-IS.

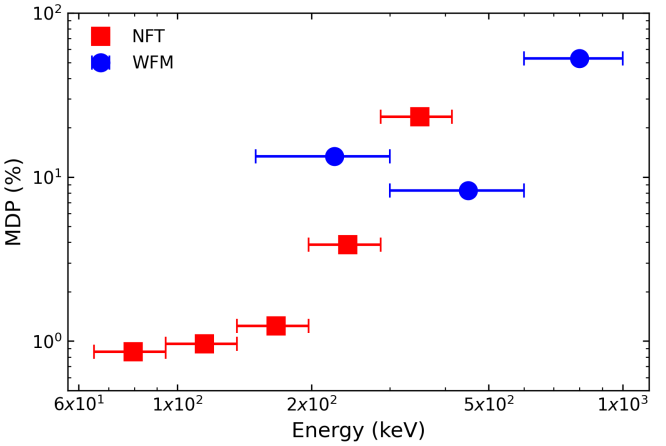

Fig. 10. Minimum detectable polarization (MDP) versus energy for a 100 mCrab source when observing with NFT and WFM-IS for 100 ks.

5. Polarimetric Sensitivity of ASTENA

In order to estimate the potential MDP of the ASTENA mission in a LEO (low Earth orbit) when observing a Crab type source, we simulated a source with a power law spectrum (normalization at 1 keV: 10.74 photons keV^{-1} s^{-2} cm^{-2}; photon index: 2.17) for each instrument individually and obtained the modulation factor and event efficiency. The simulated energy range was in accordance with the instrument energy passband: for the NFT 65 – 600 keV; and for the WFM-IS 150 keV – 1 MeV. As before, we simulated an on-axis Gaussian cone beam to mimic the 1.5 mm diameter of the Lens PSF for the NFT and a on-axis far source for the WFM-IS.

The background components were modeled in detail also using the MEGAlib environment tools for both NFT and WFM-IS using the works.[24–28] Background simulations were performed for both instruments individually and, to determine the real background for polarimetric analyses, we also performed the same selection process as the data. First we checked the events by Compton kinematics and, for the NFT data, we check if the first interaction is inside the PSF.

The effective area of the NFT was computed analytically as the product of the geometrical area of the instrument and the reflection efficiency of the lens[14] times the effective area for the WFM-IS was estimated using MEGAlib simulations.

The calculated MDP as a function of the energy when observing a 100 mCrab source for 100 ks is presented in Fig. 10. As can be seen, for energies < 200 keV the NFT presents MDP values $\sim$1%. However, above that energy it starts to substantially degrade because of the decrease of effective area of the Laue lens. For energies above 300 keV the WFM-IS presents a better MDP than the NFT meaning that the instruments can complement each other in energy bands.

6. Conclusions

In the next missions for medium energy astrophysics, polarimetry will be a fundamental requirement for the solution of important scientific problems related to the nature and geometry of the high energy cosmic sources emission. The ASTENA mission, under study as part of the European project AHEAD 2020, thanks to the high efficient, fine spectral resolution and high segmentation of the detectors onboard will be able to make polarimetry a standard way of observation by definitively opening this observation window also in the field of hard X- and soft γ-rays.

In this work we presented the results of an ongoing study which aims at a reliable and realistic evaluation of the performance in terms of polarimetry achievable with ASTENA, and obtain information for optimizing the design of the detection systems. The results show that the NFT will be able to achieve unprecedented polarametric capabilities for energies between 60 - 300 keV, while the WFM-IS will be capable to provide polarimetric measurements up to 1 MeV. ASTENA polarimetric performances show that such instruments hold the potential to address gamma-ray polarimetry with high sensitivity and contribute to expanding this new astrophysics knowledge window.

Prospect for WHIM detection in the cosmic web by *SRG/eROSITA*[1]

H. Tanimura* and N. Aghanim

Université Paris-Saclay, CNRS, Institut d'Astrophysique Spatiale, Bâtiment 121, 91405 Orsay, France

**E-mail: hideki.tanimura@ias.u-psud.fr*

Hydrodynamical simulations predict that the cosmic web contains the majority of the missing baryons in the form of plasma, called the warm-hot intergalactic medium (WHIM). However, its direct measurement through X-ray emissions has been prevented for decades due to the weak signal and the complex morphology of cosmic filaments.

We report the first statistical detection of X-ray emission from cosmic web filaments with the *ROSAT* data. We identified more than 15,000 large-scale filaments, spanning 30-100 Mpc length, in the SDSS survey and statistically detected X-ray emissions from the WHIM at 4.2 sigma confidence level using the *ROSAT* maps. Given this detection, we can expect a much more significant detection from *SRG/eROSITA* and indeed predicted the detectability of the WHIM. The prediction shows that stacking ∼2000 filaments only would lead to a 5σ detection with an average gas temperature of the WHIM as low as ∼0.3 keV.

Keywords: Clusters; intracluster medium; large-scale structure of Universe; cosmic background radiation

1. Missing baryon problem

Recent CMB observations indicate that baryons comprise 4.9% of the total energy density of the Universe,[2] and it is in agreement with the detected baryons at early times ($z > 2$), for example, through measurements of quasar absorption lines. However, at late times ($z < 2$), ∼30% of baryons have not been confirmed,[3] called the "Missing Baryon Problem." Hydrodynamical simulations predict that most of the missing baryons are expected to be in the form of hot plasma with the temperature range of 10^5–10^7 K and density of about 10–100 times the average cosmic value, referred to as the warm-hot intergalactic medium (WHIM), and to be located in filaments between galaxy clusters.[4] Therefore, extensive searches have been performed for the WHIM with far-UV, X-ray, and the thermal Sunyaev-Zel'dovich (tSZ) effect. However, the measurement is difficult because the signal is relatively weak, and the morphology of the source is complex.

2. WHIM detection with *ROSAT* data

To probe the WHIM in filaments, we used the filament catalog identified in the SDSS spectroscopic galaxies[5] and the *ROSAT* X-ray count-rate maps at six energy bands in 0.1 – 2.0 keV[6] [a]. We stacked the *ROSAT* maps at the positions of ∼15,000

[a] http://www.jb.man.ac.uk/research/cosmos/rosat/

cosmic filaments (30 to 100 Mpc at $0.2 < z < 0.6$) and detected the X-ray emissions for the first time at a significance of 4.2σ in the energy band of 0.56–1.21 keV (left panel in Fig. 1). While no significant detection was found at the other five energy bands, this result is predicted by hydrodynamic simulations,[7,8] which suggest that the relative contribution of the WHIM to the total CXB peaks at about 0.4–0.9 keV.

We performed an X-ray spectral analysis with the APEC model for the stacked signals at six energy bands and estimated the average gas density and temperature at the cores (< 2 Mpc) of the filaments (right panel in Fig. 1). The average central gas overdensity was found to be $\delta = 30 \pm 15$, assuming a cylindrical filament with a density distribution following a β-model with β=2/3. We compared this measurement with the other statistical tSZ measurement[9] and found that these results are consistent. The average gas temperature was also found to be $0.9^{+1.0}_{-0.6}$ keV, and it is a bit larger than the tSZ result of ~ 0.1 keV. This difference may imply that the gas temperature is higher at the core than at the outskirt, considering that the X-ray gas temperature was estimated within $\sim$2 Mpc from the filament spines, whereas the tSZ temperature was the average within $\sim$5 Mpc.

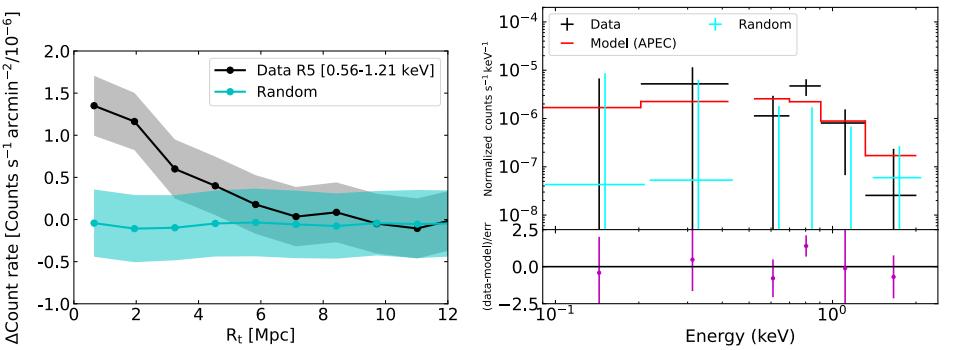

Fig. 1. *Left*: Average radial X-ray profile of 15,165 filaments in the energy band of 0.56–1.21 keV in black with the 1σ uncertainties in gray. Average radial X-ray profile from 1,000 random samplings in cyan. For each random sampling, 15,165 filaments are displaced at random positions on the *ROSAT* map. *Right*: Excesses of X-ray emission at the cores of 15,165 filaments in the six *ROSAT* energy bands in black. Amplitudes of X-ray emissions from 1,000 random samplings in cyan. Fit to the data with the APEC model in red. Ratio of data and model at each energy band is shown at the bottom in magenta.

3. Prospect of WHIM detection with *SRG/eROSITA*

A definitive statement on the gas temperature trend in filaments requires higher quality data, such as from the ongoing *SRG/eROSITA* all-sky survey. Therefore, we simulated the *SRG/eROSITA* observation of the X-ray emission from cosmic filaments based on the gas density and temperature estimated with the *ROSAT*

data and evaluated its detectability. The result shows that we can expect a $\sim 5\sigma$ detection by stacking only 100 filaments (left panel in Fig. 2).

While the detection becomes more challenging when the gas temperature is lower, we found that the stacking of ∼2,000 filaments would lead to a 5σ detection of X-ray emission, even with an average gas temperature as low as ∼0.3 keV (right panel in Fig. 2).

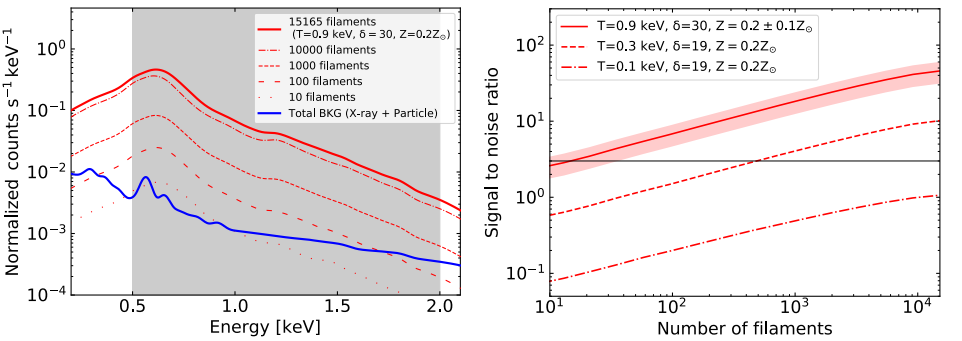

Fig. 2. *Left*: Simulated *SRG/eROSITA*'s energy spectra from the gas at the cores of the stacked 10, 100, 1,000, 10,000, and 15,165 filaments in red. The stacked spectra are calculated with overdensity = 30, temperature = 0.9 keV, and metallicity = $0.2Z_\odot$. *SRG/eROSITA*'s Background energy spectrum in blue. *Right*: Signal-to-noise ratios as a function of the number of stacked filaments are shown in red for "overdensity = 30, temperature = 0.9 keV and metallicity = $0.2Z_\odot$ at 0.5–2.0 keV", "overdensity = 19, temperature = 0.3 keV and metallicity = $0.2Z_\odot$ at 0.3–0.8 keV", and "overdensity = 19, temperature = 0.1 keV and metallicity = $0.2Z_\odot$ at 0.3–0.5 keV". Uncertainties due to the metallicity of $(0.2\pm0.1)Z_\odot$ are shown in light red area. Horizontal black line indicates a 3σ detection line.

The first detection of gravitational waves on 2015 with the Advanced LIGO and Advanced Virgo interferometers has opened a new observational window in the Universe. The last decade has also welcomed decisive discoveries in neutrino astronomy. Expected advances of gravitational wave and neutrino detectors by the end of the 2020s will mark the start of a golden era of multi-messenger astrophysics. The most promising multi-messenger sources in the high-energy sky, e.g. GRBs, AGNs, magnetars, are among the main targets for the enhanced X-ray Timing and Polarimetry (eXTP). In this proceeding, we describe the possible role of eXTP in the context of multi-messenger astronomy and in particular on the synergies with gravitational wave interferometers at the sensitivity expected by the end of the twenties.

Keywords: X-ray sources; gravitational waves; neutrinos; multi-messenger astrophysics.

1. Introduction

In the quickly evolving framework of multi-messenger astronomy, two breakthrough results have been achieved in the last few years that magnificently show the power of combining different "messengers" from the same source as well as the crucial role of high-energy observatories.

On 17 August 2017 a binary neutron star merger (GW170817) has been detected with the network of Advanced LIGO (aLIGO,[1]) and Advanced Virgo (AdV,[2]) gravitational wave interferometers. The source was found to be spatially and temporally coincident with a short Gamma Ray Burst GRB170817.[3,4] This association marked the first direct evidence that at least a fraction of short GRB progenitors are NS-NS mergers. Short GRB progenitor nature so far was based on indirect evidence collected in the last 15 years that goes from the lack of any core collapse supernova associated with a short GRB to the explosion site within the host galaxy, typically far from star forming regions (see[5] for a review). Both the burst and afterglow properties of GRB 170817 were found to be consistent with a significant inclination angle of the binary system. In particular, the afterglow properties provided

the first empirical evidence of a narrowly collimated jet and allowed to define its energy angular distribution.[6,7] Another emission component distinguished from the afterglow was also detected as a fading opt-NIR source (AT2017gfo)[8] and identified with the theoretically predicted thermal emission (kilonova) powered by the intense radioactive decay from instable heavy nuclei freshly-formed during the neutron star merger.[8,9] Past kilonova observations where claimed in few short GRBs and their identification relied on few data points (e.g.[10]). The exceptional high-quality temporal and spectral data of AT2017gfo allowed us to study in great details the kilonova properties for the first time.[11,12]

The other breakthrough discovery was achieved on 22 September 2017 when a high-energy neutrino event was detected with IceCube[13] and found to be spatially consistent with a gamma-ray emitting blazar at z=0.34 (TXS0506+056). The association has a confidence level lower than the case of GW/GRB170817 (i.e. $\sim 3\sigma$) but is an important finding that provide crucial hints on the origin of the identified diffuse flux of astrophysical very-high-energy neutrinos (10 TeV-10 PeV) detected by IceCube[14] and the possible role of blazars within most extreme particle accelerators in the Universe.

In the next few years, gravitational wave and neutrino detectors will undergo significant upgrades reaching unprecedented sensitivities. A new gravitational wave detector located in India (LIGO-India[a]) will join the current network of second generation (2G) interferometers formed by the two aLIGO in the USA, AdV in Italy and KAGRA in Japan.[15,16] Both aLIGO and AdV will reach a sensitivity larger than the nominal one with the upgraded configurations "A+" and "Virgo+"[17] during the fifth observation run (the start of which is currently scheduled for mid 2025). The completed network will be able to detect neutron star binary mergers (the most promising source for an associated electromagnetic counterpart) up to 330 Mpc, with an expected rate of few tens of detections per year (updated to the third observation run results).[17] By the end of the twenties, major upgrades are under consideration for aLIGO in the "Voyager" configuration[18] that will test some of the key technologies need for the third generation (3G) interferometers as the Cosmic Explorer (CE,[18,19]) and Einstein Telescope (ET,[20–22]) expected to be operational by mid-thirties. The "Voyager" configuration will possibly place the GW detection rate mid-way between the 2G and 3G detectors by the end of the twenties. The 3G detectors will have about one order of magnitude better sensitivity than current ones, with an expected rate of compact binary coalescences (CBCs) per year of the order of $O(10^5)$, up to distances that will cover the peak of star formation epoch and far beyond.[22]

Gravitational wave source sky localisation from the interferometer network is based on the triangulation method. By the end of the twenties, the completed GW detector network will have improved sky localisation capabilities, with average

[a]https://dcc.ligo.org/LIGO-M1100296/public

uncertainty regions of the order of few tens of square degrees for CBCs.[17] At distances larger than $\sim$ 100 Mpc, this scenario challenges the identification of the electromagnetic counterparts at optical wavelengths due to the large number of transient sources expected in such large areas and the incompleteness of galaxy catalogs above 100 Mpc. On the contrary, the high-energy transient sky is much less populated and gamma-ray or X-ray counterparts detected with all sky monitors might represent the most suitable way to pinpoint the GW source in the sky.

The GW source localisation uncertainties strongly depends on the presence of a network. This is still uncertain for the 3G interferometers during the thirties. A single GW detector such as ET, thanks to its sensitivity at low frequency, is able to localize about 100 binary neutron star merger per years within a few tens of square degrees up to a redshift of 0.3. These sources are detected before the mergers (some of them also few hours before the merger). For a network of detectors including ET and CE, the number of well localized events increases of an order of magnitude. However, going to large distances the sky-localization becomes of hundreds of square degrees for a large majority of events (e.g.,[22,23]). Early warnings from GW detectors allows ground and space-based telescopes to slew onto the identified sky region before the advent of the expected electromagnetic transient emission. Early warning alerts of the order of few minutes for the most nearby sources (i.e. NS-NS mergers at few tens of Mpc) are planned also for the 2G next observation runs[b].

For neutrino detectors, the Km3NeT[24] in the Mediterrean Sea will provide IceCube comparable sensitivites in the Northern Emisphere on the second half of the twenties and it will work in synergies with the Gigaton Volume Baikal late neutrino detector. In the Southern Emisphere, IceCube-gen2 will gradually increase the current IceCube sensitivity up to one order of magnitude,[25] boosting the current astrophysical neutrino detection rate to values that will significantly increase the chances to find the electromagnetic counterparts. The neutrino sky localization accuracy depends on neutrino flavour, where long tracks topology (for ν_μ) provide angular resolution down to 0.1-0.2 deg and a 2π sr sky coverage, while cascade topology (for ν_e and most ν_τ) angular resolution are typically 3-5 deg for the whole 4π sky, thus still requiring an electromagnetic counterpart and detectors with sky localization capabilities better than few arcmin to pinpoint the host galaxy and/or identify the source.

The launch of the enhanced X-ray Timing and Polarimetry mission eXTP,[26] currently scheduled by 2027[c], coincides with the middle/final stages of the above described major upgrades of neutrino and gravitational wave detectors. The recent breakthrough results described above, point to the gamma-ray bursts and active galactic nuclei among the most promising classes of multi-messenger sources that will be observed in the next years. Further promising candidates are represented by

[b] $https://emfollow.docs.ligo.org/userguide/early_warning.html$
[c] https://www.isdc.unige.ch/extp/

magnetars and core collapsing supernovae. All these sources are among the main targets for eXTP and a number of white papers describe all the science we will be able to do with eXTP.[27–30] The onboard wide field monitor (WFM, 2-50 keV, 3.7 sr field of view), with few arcmin-scale sky localization capabilities, and two sets of focusing telescope arrays with spectroscopic and polarimetric capabilities (SFA and PFA), will allow eXTP to play a crucial role in finding and characterizing the electromagnetic counterparts of the gravitational wave and neutrino sources by the end of the twenties.

In the following sections we focus on the capabilities of eXTP to observe two specific classes of multi-messenger sources: the compact binary coalescences (CBC) formed by two neutron stars (NS-NS) or a neutron star and a stellar-mass black hole (NS-BH), and core collapsing massive stars (ccSNe). For NS-NS mergers and ccSNe, a metastable or stable neutron star remnant may form after the main event. Both NS-N/NS-BH and ccSNe, as well as the possible NS remnant, have a number of theoretically expected emission components in the electromagnetic spectrum and in particular at high energies.

2. NS-NS/NS-BH mergers

Several electromagnetic components are expected in the soft/hard X-ray bands after the merger phase of coalescing NS-NS/NS-BH systems. A short GRB, possibly accompanied by a soft extended emission (see below), is expected soon after[d] the coalescence if the observer line of sight lies along the jet axis or within a certain angle range that depends on the combination of the source distance, the jet energetic angular distribution and the detector sensitivity. The collimated nature of gamma-ray emission implies that only a fraction of GW-detected NS-NS/NS-BH can be observed as short GRBs. To make a rough estimate, by assuming that all NS-NS/NS-BH produce a GRB, the number of GW+GRB detection is $f_b = (1-cos\theta_{jet})$ times lower, where f_b can be as low as 0.001 for $\theta_{jet} \sim 2-3$ deg. Interestingly, recent results on the jet structure based on the observation of GRB170817,[31] shows that at large viewing angles gamma-ray emission get fainter but also softer, thus allowing sensitive wide field monitors to cover energies down to a few keV, as eXTP/WFM, best suited for detecting the electromagnetic counterpart of most nearby NS-NS/NS-BH events that are more likely off-axis. Simultaneous detection of GRB+GW can provide a wealth of information on jet launching mechanisms exploiting for instance the temporal delay between the GRB trigger and the GW detection. Also a non-detection of a GRB counterpart can provide useful insights on jet formation efficiencies in NS-NS/NS-BH.

The impact of the jet with the circumburst environment gives rise to an afterglow emission that, depending on the viewing angle from the jet axis, it can show an initial steep decay followed by a plateau and then a typical $t^{-\alpha}$ decay (with $\alpha \sim 1-2$), or an

[d]For GW170817, the short burst was observed 1.7 seconds after the merger epoch.[4]

initial slow rising behaviour followed by a late time power law decay in case of large viewing angles. At very late time, e.g. months up to years after the NS-NS/NS-BH merger, the impact of the nearly isotropic ejecta of neutron-rich matter released during the merger, may eventually produce a mildy-relativistic blast wave from which synchrotron radiation could be observed in X-rays (e.g.,[32] see also §2.1.3). For NS-NS mergers, if a NS remnant is formed, nearly isotropic X-ray emission produced from the pulsar nebula might escape if successfully ionizes the surrounding ejecta of matter released during the merger. Such non-thermal X-ray emission is expected on timescales of the order of days for certain values of the pulsar magnetic field and ejecta mass and with luminosities up to $\sim 5 \times 10^{44}$ erg s^{-1}.[33,34]

We will see in the next sections how eXTP will play an important role in detecting these high-energy components, significantly contributing to multi-messenger observational campaigns by the end of the twenties.

2.1. *eXTP and GRB 170817-like sources*

In this section we present preliminary results from data simulations of X-ray emission from a GRB170817-like source observed with eXTP. For these simulations we used calibration files released by March 2021 and the data analysis software package XSPECv12.10.[35]

2.1.1. *Prompt emission*

GRB 170817 is so far the only short GRB that has been associated with a NS-NS merger system detected through GW emission (see §1). Despite a high-energy signal rather typical for short GRBs, with duration of $\sim$ 2s and peak photon flux of 3.7 ± 0.9 ph cm^{-2} s^{-1} in the 10-1000 keV band,[36] given the very small distance of the source ($\sim$ 40 Mpc,[3]), the isotropic equivalent luminosity $L_{iso} = 1.6 \times 10^{47}$ erg s^{-1}[37] is several orders of magnitude lower than the average value for short GRBs ($\sim 10^{52}$ erg s^{-1}, see e.g.[38]). According to Goldstein et al.,[36] the burst spectrum is best fitted by a power-law model with exponential cut-off $f(E) = A(E/E_0)^{\alpha} e^{-E(2+\alpha)/E_p}$ in the first 0.6 s, with $\alpha = -0.62 \pm 0.40$, peak energy[e] $E_p = 185 \pm 62$ keV, 10-1000 keV flux $(3.1 \pm 0.7) \times 10^{-7}$ erg cm^{-2} s^{-1} and fluence $(1.8 \pm 0.4) \times 10^{-7}$ erg cm^{-2}. During the tail of the burst, the spectrum is best fitted by a black-body with KT=(10.3 ± 1.5) keV, flux $(0.5 \pm 0.1) \times 10^{-7}$ erg cm^{-2} s^{-1} and fluence $(0.61 \pm 0.12) \times 10^{-7}$ erg cm^{-2} in the 10-1000 keV. By using these best-fit models, and introducing photoelectric absorption with equivalent hydrogen column density[f] $N_H = 7.5 \times 10^{20}$ cm^{-2},[36] we perform simulations of eXTP/WFM observations of the main burst in the 2-50 keV energy band and find that a GRB 170817-like burst at the same distance could be

[e]The peak energy is the cut-off energy multiplied by $(\alpha + 2)$

[f]based on the host galaxy NGC4993 dust extinction $A_V = 0.338$

confidently detected ($\sim 7\sigma$) during the first 0.6 s, if spectral parameters were at the 1σ soft side of the error margins, confirming past results.[27] We estimate that a GRB170817-like source could be detectable with eXTP/WFM under this spectral assumption up to about 70 Mpc.

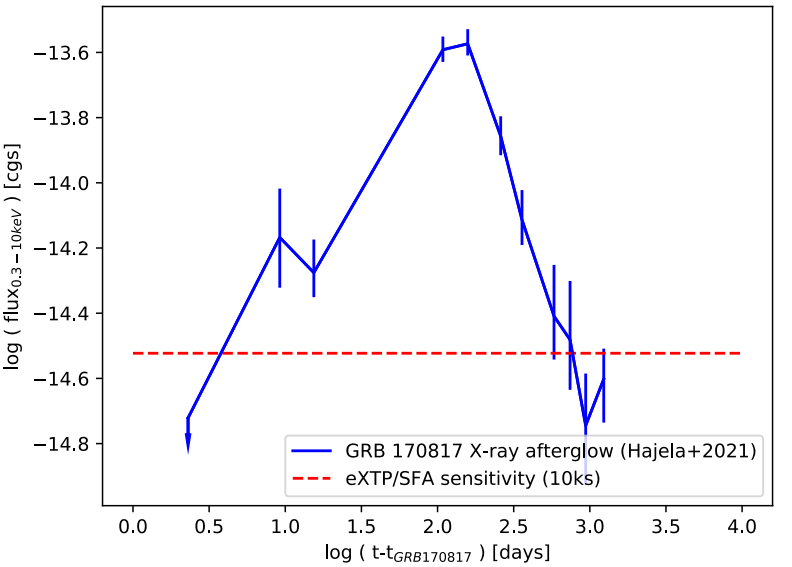

Fig. 1. X-ray (0.3-10 keV) flux of the short GRB 170817 afterglow that was associated with a NS-NS merger progenitor. Data are from Hajela et al. 2021 and references therein. The eXTP/SFA sensitivity will allow us to monitor a similar source from the very first phases up to the late ones, providing accurate sky localization. Horizontal line indicates the eXTP/SFA sensitivity for 10 ks of exposure from Zhang et al. 2016 and[26] computed in the 0.3-10 keV by assuming an absorbed power law model with phton index $\Gamma = 1.7$ and $N_H = 5 \times 10^{20}$ cm^{-2}.

2.1.2. *Afterglow emission*

The X-ray afterglow emission of GRB 170817 was detected with Chandra only 9 days after the merger as a faint source spatially coincident with the optical counterpart AT2017gfo and with flux $\sim 5 \times 10^{-15}$ erg cm^{-2} s^{-1} (0.3-10 keV,[39]). GRB170817 X-ray afterglow showed a slow rising behaviour that reached a peak of the emission after 100 days, with X-ray peak flux of a few 10^{-14} erg cm^{-2} s^{-1} (see Fig. 1). The overall properties of GRB170817 are in good agreement with the predictions for a GRB observed with a large inclination angle ($\sim 20-40$ deg) with respect to the jet axis. Given the eXTP/SFA sensitivities by assuming 10 ks of exposure ($\sim 2\times10^{-15}$ in the 2-10 keV energy band and $\sim 5\times10^{-16}$ in the 0.5-2 keV energy band, see Zhang et al. 2016), an X-ray afterglow of a GRB 170817-like source could be observed at almost all epochs, if accurate source sky localization is provided. The light curve

long monitoring provided by eXTP/SFA is crucial to disentangle among different jet structure modellings that in turn encode the physics of jet formation and launching mechanisms in GRBs.

2.1.3. *Very late time X-ray emission*

Currently, the X-ray emission of GRB 170817 is still detectable and shows an intriguing possible rebrightening phase 4 years after the merger epoch.[40] Among the possible interpretations, this rebrightening could be the evidence of the theoretically predicted non-thermal emission produced by the impact of the kilonova ejecta into the circumburst medium,[32,41] though other interpretations are under investigations.[42] Measured spectrum during this phase assuming a power-law model, has photon index $\Gamma = 1.6$ and an integrated flux of 2.5×10^{-14} erg cm^{-2} s^{-1} in the 0.3-10 keV energy range.[32] We find that by assuming the spectral parameters provided by,[32] such late time X-ray emission could be detected with eXTP/SFA at more than 5σ level with 20 ks of exposure.

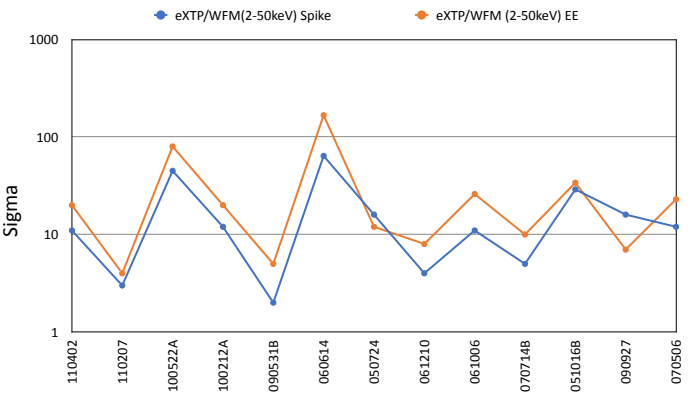

Fig. 2. Detection significance of a sample of short GRB spikes (blue) with Extended Emission (EE, orange). The x-axis shows the short GRB names, where the last 8 has measured redshift and cover a range from z=0.125 for GRB060614 to z=2.31 for GRB070506.

2.2. *Short GRB with Extended Emission*

An interesting perspective that potentially can increase the simultaneous GRB+GW detection is represented by the subclass of short GRBs that, following the main spike with hard spectral properties, show a prolongued softer and fainter Extended Emission (EE) that lasts after few tens of seconds.[43–46] The fraction of short GRBs with EE is still very uncertain and from high-energy detector catalogues range from $\sim 2 - 20\%$. However, recent studies over a large sample of short GRBs detected

with the coded mask telescope onboard the Neil Gehrels Swift Observatory (Swift, hereafter,[47]) and for which the X-ray telescope (XRT) observations could start during the EE, showed that providing a spectral coverage down to sof X-rays (i.e. $\sim$ few keV), the fraction of short GRBs with EE can be as high as 50% or more.[48] Among the possible hypothesis on the origin of the extended emission there is the presence of a magnetar formed soon after the merger of two neutron stars.[49,50] The important consequence in this case is that the extended emission component is expected to have a much lower degree of collimation with respect to the main spike that characterizes the short GRB.[33,50] If so, the EE detection rate can be in principle higher than short GRBs, making wide field monitors sensitive to the X-ray band as eXTP/WFM best suited to detect the electromagnetic counterparts of a potentially large fraction of NS-NS mergers.

We simulate 5 short GRB with EE with measured spectral parameters from Fermi/GBM and Swift/BAT joint analysis plus 8 short GRB with EE observed with Swift/BAT with known redshift. We take best fit parameters from Kaneko et al.[44] For these simulations we used calibration files released by March 2021 and the data analysis software package XSPECv12.10.[35] We find that EE component is always detected with eXTP/WFM and in most cases with better significance than the hard spike (see Figure 2).

2.3. *Polarisation of GRB jets*

2.3.1. *The prompt emission*

Despite the fact that GRBs have been observed more than forty years, the basic properties of the GRB jets are not yet constrained. We still can not discriminate baryonic jets[51,52] from ones dominated by the Poynting flux[53,54] by only analysing the spectral and temporal properties of short lasting prompt emission pulses ($\sim$0.1 s) at the keV-MeV energy range (see[55] and[56] for a review). We also do not have a clear understanding of the dissipation processes that lead to the GRB production. Our knowledge is limited by the lack of an interpretation of the GRB spectra which are typically modelled by the two broken power laws smoothly connected at $\sim$ 200 keV for LGRBs and at higher energies for SGRBs.[57] The observed spectra are too narrow to fit the fast cooling synchrotron radiation model and they are too broad compared with the simple thermal emission.[57,58] The absence of a single and straightforward emission mechanism to explain the typical GRB spectra has left us with big number of diverse physical models that correspond to very different GRB jet models. We can roughly classify the GRB production models by their dissipation side. The "standard" model assumes that the prompt emission is produced above the jet photosphere by the synchrotron emission of the non-thermal electrons that are produced by the internal shocks.[59,60] The "expected" parameters of the internal shocks model return fast cooling regime of the synchrotron radiation to dominate in the prompt phase, however it contradicts the observed values of the photon indices

at the low energies.[58] Other class of models assume that the dissipation of the jet takes the place below the jet photosphere via the radiation dominated shocks.[61,62] The complex nature of the formation of the final spectrum via many Compton scatterings allows to produce spectra much broader than a simple thermal ones, thus close to the observed GRB spectra. However, it remains quite challenging to explain the observed variability, the power law structure of the high energy tail of the GRB spectra and the long lasting X-ray tails of the GRB pulses in these models.[63] There are numerous effects that can modify the spectral expectations from internal shocks model or any other optically thin synchrotron sources (e.g. non-thermal particles from magnetic re-connection), including the anisotropy of electron's pitch angles or presence of an external source of photons (see[64] for a brief review). While all these models could explain some of the observed GRB spectra, or at least partially (at the low or the high energy part), their prediction on the level of polarisation and the evolution of the polarisation angle is quite different, also depending on the structure of the local magnetic field (see[65] for a review). Therefore, the polarisation measure of the prompt phase is crucial for discriminating among GRB jet models including the acceleration processes (the magnetic field orientation).

So far the attempts to measure the GRB polarisation over short time-scales in the soft γ-rays returned inconclusive results due to contradictions between instruments and methods of data reduction performed by the Gamma-Ray Burst Polarimeter (GAP) (Yonetoku et al. 2011), POLAR,[66] and the Astrosat CZTI[67] instruments. The future γ-ray polarimeters, such as POLAR-2, LEAP and SPHiNX, have the capabilities to improve the polarisation measure accuracy of the prompt emission phase. However, measuring the polarization in the X-rays is equally interesting and has its own advantages. While the prompt emission pulses are very short in the soft γ-rays, we do observe regularly their tails (X-ray steep decay phase) for much longer time (100-1000 s) in 0.3-10 keV thanks to Swift/XRT. The X-ray steep decay is quite bright and starts at $\sim 10^{-7}\,\mathrm{erg\,s^{-1}\,cm^{-2}}$ at the peak of the prompt pulse and drops in two orders of magnitude in 100-1000 s. This phase is modelled as remnant of the prompt emission, i.e. the emission we observe when the GRB pulse is diminished at the jet co-moving frame.[68] Recently, it was demonstrated that X-ray steep decay is the lower energy prompt emission originated by the adiabatically cooling jet after its heat source is switched off.[69] Measuring X-ray polarization in the steep decay phase by the Polarimetry Focusing array (PFA) onboard eXTP would be a direct probe of the prompt emission polarisation (see[70]). The sensitivity of PFA is enough to constrain the linear polarisation degree for exposures of 100-1000 s given the extraordinary brightness of the X-ray steep decay phase. It requires a precise sky localisation of each detected GRB by the wide field γ or X-ray instruments, comparable with the extremely narrow FoV of PFA. The localisation level of arcminutes are expected to be provided by the eXTP/WFM and also by the next generation nano-satellite detectors such as HERMES.[71] Therefore, the prompt communication between eXTP instruments and advanced networks of γ-ray

telescopes could provide a unique tool to study early X-ray polarisation. The presence of precursors and the quiescent periods in the temporal structure of LGRBs could be useful to send early trigger to detect bright X-ray counterparts of GRBs by PFA.

While *Swift*/XRT has been able to detect the steep decay phase of LGRBs, it is still technically challenging to promptly slew in the case of SGRBs. Given the spectral differences between long and short GRBs, one would expect physical differences between their jets and the dissipation processes. Therefore, the early detection of the X-ray emission from SGRBs and the measurement of its polarisation is of a great interest. The early warning and localisation of GWs prior to the BNS merger by the next generation GW detectors, such as the Einstein Telescope,[72] could be a unique trigger for the detection of the early X-ray polarisation of the the tail of the prompt emission from SGRBs.

2.3.2. *The afterglow emission*

Although we have very little knowledge on the physics of the prompt emission production, GRB afterglow emission (lasting for days) has a quite convincing interpretation. It is widely accepted that the dissipation of the GRB jet in the circumburst medium via shocks produces afterglow emission.[73–75] There have been several indications of detection of the linear polarisation in the late afterglow emission at the level of few percent[76] and a detection of circular polarisation in the afterglow of GRB 121024A.[77] The linear polarisation of level of few percent has been found at very early times,[78] when the emission is dominated by the reverse shock propagating into the GRB jet ejecta. Thus these measurements result to be essential for probing the shock physics by constraining the orientation of the magnetic field relative to the bulk motion, as well as for understanding the nature of the GRB jet by itself (reverse shock). Furthermore, nearby GRB sources can be detected off-axis, as the multi-messenger event of GW 170817/GRB 170817A. An upper limit of 12 percent in the linear polarisation at 2.8 GHz was obtained 244 days after the binary neutron star merger.[79] This upper limit allowed us to establish that the magnetic field has a finite parallel component, calling for turbulence amplified magnetic field in the external shock.[80]

X-ray domain in the physics of the GRB afterglow has a special importance for the following reasons. While the radio, optical and Very High Energy emissions in the afterglow phase are typically consistent with the standard external shocks model, *Swift* has discovered, that roughly half of the X-ray afterglow emission deviated from the standard forward shock emission, showing a long lasting (up to $\sim 10^4$ s) plateau phase, which is characterised by nearly constant flux. The X-ray plateau emission is can be produced by the additional energy input from the GRB central engine (e.g. newborn magnetar)[68] or it can be caused by the viewing angle effects[81] or by the delayed prompt emission from the jet wings.[82,83] In either case, the measure of the polarisation would be essential for constraining the physics

of this mysterious GRB phase, simply because the polarisation would probe the structure of the magnetic field of the emission surface. From the observational perspective, the plateau phase has some advantages; it appears later compared to the steep decay phase giving more time to slew on, lasts longer ($\sim 10^4$ s), it is relatively bright ($\sim 10^{-10}\,\mathrm{erg\,s^{-1}\,cm^{-2}}$ comparable with the PFA sensitivity) and with absence of significant spectral evolution, which could remove polarisation. In the era of the Einstein Telescope, it would be also possible to constrain the BNS postmerger signal for relatively nearby sources. Combining the information from the BNS postmerger signals together with the X-ray polarisation from the plateau phase will be extremely powerful to shed light on our understanding of the origin of the central engine powering SGRBs.

Another intriguing possibility to probe the prompt emission is to measure the polarisation of the late-time X-ray flares. *Swift* has discovered numerous X-ray flares superimposed to the afterglow emission.[84] These flares appear up to 10^5 s after the GRB detection and their variability suggests their internal nature, i.e. they could be hardly produced by the external shocks. Therefore, they are often interpreted as late-time prompt emission. Their late-time appearance and relative brightness increases the chances for PFA to measure their linear polarisation,[85] thus providing complementary observations to the the next generation γ-ray polarimeters. From one side, the X-ray flares polarisation measurements would probe the prompt emission zone, and on the other side, the comparison between the polarisation measurements at early times in γ-rays and at late times in X-rays would finally help us to establish the nature of the late time X-ray activity.

3. Core collapse supernovae and magnetars

Core collapse supernovae (ccSNe) have been claimed as another potential class of high-frequency gravitational wave sources,[86–88] as well as neutrino sources,[89] that current and/or future ground-based GW detectors and neutrino detectors may reveal in the next years. The ccSNe energy output transferred with GWs however is still very uncertain depending on the rather unnown explosion mechanism. Recent modelling contraints on possible GW energy values, obtained from a search of GW transients associated with optically detected ccSNe within ~ 20 Mpc during the first two observational runs of aLIGO and AdV (between 2015 and 2017), suggest that ccSNe GW detection may happen in the next years for sources up to few tens of Mpc in a few, very optimistic scenarios.[90] The GW signal detection from ccSNe, possibly combined with neutrinos detection, represents a unique opportunity to probe the inner dynamics inaccessible to electromagnetic observations. The electromagnetic counterpart of ccSNe plays a key role in allowing to confirm or discard the likely very faint GW signal by providing a precise sky localization and an estimate of the epoch of the explosion.

At high-energies, the best GW-detected ccSNe electromagnetic counterparts would be the typical long GRBs due to their brightness and the expected temporal

proximity to the epoch of the GW burst originating from the core collapse. The rate of typical long GRBs, however, is expected to be extremely low due to the small fraction of ccSNe known to be associated with such energetic events (only about few %, e.g.[91]), and to the combination of the GRB collimated nature and the short distances that GW detectors may reach for this type of burst signals. However, a subclass of anomalously faint and soft long GRBs, named Low Luminosity GRBs (LLGRBs), have been suggested to represent a distincted class of long GRBs that populate the local Universe at a much higher rate (up to 10^3 times the typical long GRBs). The redshift distribution of LLGRBs detected so far is well below 1, where the most nearby was detected at z=0.0085 (37 Mpc).[92] These properties make LLGRBs an interesting class of sources that may enhance the chances of simultaneous detection with GWs with high-energy wide field monitors. LLGRBs are also softer than typical long GRBs and this highlight the role of wide field monitors with peak sensitivity between few to few tens of keV as eXTP/WFM. We simulated how eXTP/WFM would detect GRB 060218, a typical LLGRB observed with Swift/BAT. This was a close GRB at 139 Mpc showing an unusual long and soft burst, with duration 2740s.[93] The burst was best fitted by a simple power law spectrum in the 15-150 keV with photon index $\Gamma = 2.5 \pm 0.1$, fluence of 5.8×10^{-6} erg cm^{-2} and peak flux 2×10^{-8} erg cm^{-2} s^{-1}. By simulating with XSPECv12.0 the eXTP/WFM observations using the most recent calibration files we find that with 1ks of exposure this burst could have been clearly detected with significance of $\sim 40\ \sigma$.

Another electromagnetic counterpart at high-energy is represented by the X-ray emission from the ccSNe shock breakout (SBO). The advantage of such component with respect to LLGRBs is that it is thought to be not collimated. However, the SBO phenomenology lack of statistics so far, with only one event observed (XRO 080109/SN2008D,[94]). The 0.3-10 keV spectrum of XRO080109 was consistent with a power law with photon index $\Gamma = 2.3 \pm 0.3$, equivalent hydrogen column density $N_H = 6.8^{+1.8}_{-1.5} \times 10^{21}$ cm^{-2} and peak flux of 7×10^{-10} erg s^{-1} cm^{-2}.[94] Such low fluxes could not had been detected by the majority of current wide field monitors. Indeed, its discovery happened serendipitously by falling within the Swift/XRT field of view while performing a follow-up campaign of another source in the very same galaxy. By assuming the best fit spectral model of XRO080109, very preliminary simulations with eXTP/WFM with 400 s of exposure show that this source would not be detected, confining the SBO detection with eXTP/WFM within our Galaxy.

4. Conclusions

The eXTP expected launch date and lifetime are timely for a full synergy with upgraded second generation GW detectors and with next generation neutrino detectors. Among the most promising multimessenger sources there are the compact binary mergers from which the high-energy electromagnetic counterpart is expected in the form of short GRBs and their afterglows and possibly additional X-ray emission,

yet to be confirmed, as from the impact of the kilonova with the circumburst medium. We have shown how eXTP/WFM can observe short GRBs, including the "Extended emission" observed in a fraction of short GRBs. The eXTP/SFA could have monitored almost all the evolution of the associated X-ray afterglow of GRB 170817 up to very late times and the eXTP/WFM detect the soft component of the prompt emission up to 70 Mpc. Both neutrino and GW are expected from cc-SNe, a subclass of which is the progenitor of long GRBs and in particular of the much more numerous low luminosity GRBs that are populating the nearby Universe. eXTP/WFM can play a crucial role in detecting the associated GRB and providing accurate burst timing and sky localization that will help in refining GW/neutrino event detection confidence and parameter estimation. In particular, the eXTP/WFM sky localization will allow us to trigger follow-up campaigns by next generation facilities as ELT, SKA, CTA, etc. to characterize GW sources with unprecedented sensitivities. eXTP/SPA is capable to detect the GRB prompt and afterglow emission polarisation to disentangle among different jet launching mechanisms as well as to shed light on the nature of the late time activity observed in the X-ray afterglow of several events.

CALET on the ISS: The first 5 years

Pier Simone Marrocchesi* for the CALET Collaboration†

Dept. of Physical Sciences, Earth and Environment, Via Roma 56, I-53100 Siena, Italy
and INFN Sezione di Pisa, Largo Bruno Pontecorvo 3, I-56127 Pisa, Italy
**E-mail: piersimone.marrocchesi@pi.infn.it*

Abstract—The CALorimetric Electron Telescope CALET is collecting science data on the International Space Station since October 2015 with excellent and continuous performance. Energy is measured with a deep homogeneous calorimeter (1.2 nuclear interaction lengths, 27 radiation lengths) preceded by an imaging pre-shower (3 radiation lengths, 1mm granularity) providing tracking and 10^{-5} electron/proton discrimination. Two independent sub-systems identify the charge Z of the incident particle from proton to iron and above (Z<40). CALET measures the cosmic-ray electron+positron flux up to 20 TeV, gamma rays up to 10 TeV, and nuclei up to 1 PeV. In this paper, we report the on-orbit performance of the instrument and summarize the main results obtained during the first 5 years of operation, including the electron+positron energy spectrum and the individual spectra of protons, heavier nuclei and iron. Solar modulation and gamma-ray observations are also concisely reported, as well as transient phenomena and the search for gravitational wave counterparts.

Keywords: Cosmic rays; high energy astrophysics; space-borne experiments.

1. INTRODUCTION

CALET is a cosmic-ray experiment designed for long-term observations of charged and neutral cosmic radiation on the ISS. The instrument is managed by an international collaboration led by the Japanese Space Agency (JAXA) with the participation of the Italian Space Agency (ASI) and NASA. It was launched on August 19, 2015 with the Japanese carrier H-IIB, delivered to the ISS by the HTV-5 Transfer Vehicle, and installed on the Japanese Experiment Module Exposure Facility (JEM-EF). The science program of CALET addresses several outstanding questions of high-energy astroparticle physics including the origin of cosmic rays (CR), the possible presence of nearby astrophysical CR sources, the acceleration and propagation of primary and secondary elements in the galaxy, and the nature of dark matter. The design of CALET is optimised for high precision measurements of the electron+positron spectrum with an accurate scan of the energy interval already covered by previous experiments and its extension to the region above 1 TeV. Given the high energy resolution of CALET for electrons, a detailed study of the spectral shape might reveal the presence of nearby sources of acceleration as well as possible indirect signatures of dark matter.[1,2]

With its individual element resolution in the charge identification of cosmic rays, CALET is also carrying out direct measurements of the spectra and relative

†See the last page for the full authors list.

abundances of light and heavy cosmic nuclei[3,4] from proton to iron, in the energy interval from $\sim$50 GeV (10 GeV/n) for the lighter (heavier) nuclei to several hundred TeV. The abundances of the rare CR trans-iron elements up to Z$\sim$40 are studied with a dedicated program of long term observations.[5]

2. THE CALET INSTRUMENT

The CALET main telescope is an all-calorimetric instrument comprised of three sub-detectors. The CHarge Detector (CHD) is positioned at the top of the apparatus and consists of a two layered hodoscope of plastic scintillators paddles (14 paddles per layer). It performs the charge identification of individual nuclear species, providing a measurement of the charge Z of the incident particle over a wide dynamic range (from Z = 1 up to Z = 40).[6] The IMaging Calorimeter (IMC) is a fine grained sampling calorimeter, segmented longitudinally into 16 layers of scintillating fibers (with 1 mm^2 square cross-section), read out individually and arranged in pairs along orthogonal directions. Each pair is interleaved with thin tungsten absorbers (for a total thickness of 3 X_0). It reconstructs the early shower profile and the impinging particle trajectory with good angular resolution, while providing also a redundant charge measurement.[1] The third detector is the Total AbSorption Calorimeter (TASC), an homogeneous calorimeter with 12 layers of lead-tungstate (PWO) logs arranged in pairs along orthogonal directions. With its 27 X_0 thickness and shower imaging capability, it measures electrons and gamma-rays with an excellent energy resolution, providing high discrimination against hadronic cascades. The total thickness of the main telescope is equivalent to 30 X_0 and 1.3 proton interaction lengths (λ_I), the geometrical factor is 0.12 m^2 sr. A more detailed description of the instrument can be found in Ref. 7 and in the Supplemental Material (SM) of Ref. 9.

3. FLIGHT OPERATIONS AND CALIBRATIONS

The commissioning of CALET aboard the ISS was successfully completed at the beginning of October 2015. Since then, the instrument has been taking science data continuously with no significant interruptions.[2] The on-orbit operations are controlled via the JAXA Ground Support Equipment (JAXA-GSE) in Tsukuba by the Waseda CALET Operations Center (WCOC) at Waseda University, Tokyo.

As of April 30, 2021 a total observation time of more than 2027 days was integrated with a live time fraction $\sim$85% of the total time, and $\sim$2.7 billion events collected above 1 GeV. The exposure with the high-energy (HE) trigger mode, designed to maximize the collection power for electrons above 10 GeV, and other high-energy shower events was $\sim$ 178 m^2 sr day.

Energy calibrations of each channel of CHD, IMC, and TASC is performed with penetrating proton and He particles selected in-flight by a dedicated trigger mode. Raw signals are corrected for light output non-uniformity, gain differences among the channels, position and temperature dependence, as well as temporal

gain variations.[7,8] Correlations among the four gain ranges for each TASC channel are calibrated with flight data, and responses from consecutive ranges are linked together to provide a seamless transition. In this way, a dynamic range spanning more than six orders of magnitude is achieved, allowing observations from one minimum ionizing particle to 1 PeV showers.

4. COSMIC-RAY DIRECT MEASUREMENTS WITH CALET ON THE ISS

4.1. *The Electron Spectrum*

The CALET collaboration reported their first measurement of the inclusive electron+positron spectrum in the energy range from 10 GeV to 3 TeV (Ref. 9) within a fiducial subset of the acceptance. Soon after, the DArk Matter Particle Explorer (DAMPE) collaboration published their all-electron spectrum in the energy interval from 25 GeV to 4.6 TeV (Ref. 10).

The latter publication was followed by a number of papers speculating about the origin of a possible peak-like structure near 1.4 TeV in DAMPE data. An updated version of the CALET all-electron spectrum was published, covering the energy

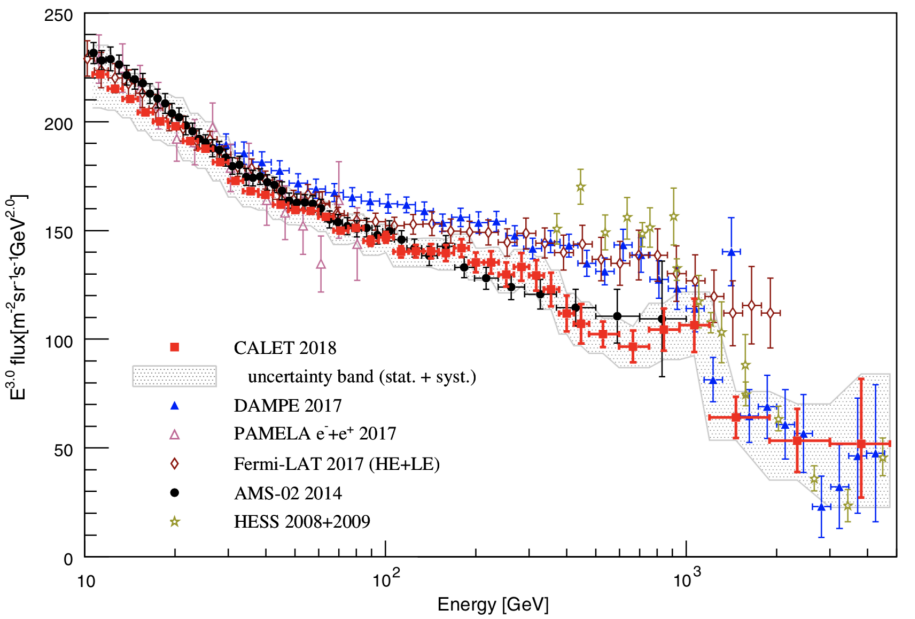

Fig. 1. Direct measurements of the electron + positron flux by space-borne experiments including,[10,11 12–14] and from ground-based experiments.[15,16] The CALET 2018 data[11] are shown as red filled circles in the energy interval 11 GeV to 4.8 TeV. The width of each bin is shown as a horizontal bar, statistical errors as vertical bars. The gray band indicates the quadratic sum of statistical and systematic errors (not including the uncertainty on the energy scale).

range from 11 GeV to 4.8 TeV (Ref. 11) with 780 days of flight data and the full geometrical acceptance. It reported a new analysis with doubled statistics at $E>$ 475 GeV and included one additional energy bin between 3 and 4.8 TeV (Figure 1). The width of each bin is shown as a horizontal bar, the statistical errors as vertical bars, while the gray band is representative of the quadratic sum of statistic and systematic errors. A comprehensive study of the systematic uncertainties was performed as described in Refs. 9, 11 and Supplemental Material therein. A constant electron identification efficiency of 70% was achieved above 30 GeV, with a proton contamination level of 2–5% below 1 TeV and ∼10–20% above.

Taking the currently available experimental data at face-value, we notice that the all-electron spectrum data seem to fork into two groups of measurements: AMS-02 + CALET and Fermi/LAT + DAMPE, with good consistency within each group, but with only marginal overlap between the two, possibly indicating the presence of unknown systematic errors. The CALET spectrum is consistent with AMS-02 below ∼1TeV where both experiments have a good electron identification capability albeit using different detection techniques. CALET observation of a flux suppression above ∼1TeV is consistent with DAMPE within errors. No peak-like structure was found at 1.4 TeV in CALET data, irrespective of the energy binning. After re-binning with the same set of energy bins as DAMPE, an inconsistency between the two measurements emerged[11] with a 4 σ significance, the latter including the systematic errors quoted by both experiments.

New results on the analysis of electrons based on the first five years of CALET observations will be presented at the upcoming ICRC2021 conference.

4.2. *The Proton Spectrum*

Cosmic-ray energies from the GeV scale to the multi-TeV region have been explored – in separate subranges – by magnetic spectrometers (e.g., BESS-TeV, PAMELA, and AMS-02), calorimeters (e.g., ATIC, CREAM, NUCLEON, and DAMPE) and Cherenkov / Transition Radiation instruments (e.g., TRACER). In the intermediate energy region from 200 GeV to 800 GeV a deviation from a single power-law (SPL) was observed in both proton and helium spectra by CREAM,[17–19] PAMELA[20,21] and confirmed with high statistics measurements by AMS-02,[22] CALET,[23] and DAMPE.[24]

The first proton paper published by CALET[23] reported a proton flux measurement where, for the first time, a single space-borne instrument was able to cover the whole interval of proton energies from 50 GeV to 10 TeV thanks to its large dynamic range. The proton flux was extracted from the data collected from October 13, 2015 to August 31, 2018 (1054 days) on the ISS using only 40% of the total acceptance. A detailed study of the systematic uncertainties was reported in the same paper and in the Supplementary Material therein.[23] This is of particular relevance because CR flux measurements are well known to be affected by relatively large systematic errors, often specific of each instrument. CALET proton data (Fig. 2)

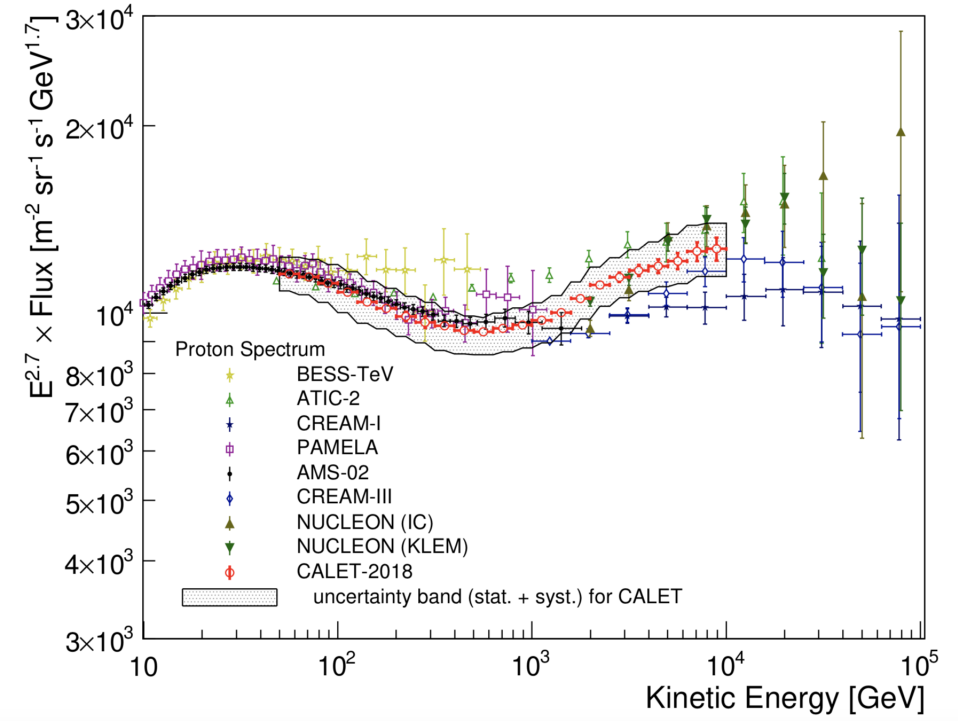

Fig. 2. Cosmic-ray proton spectrum measured by CALET from 50 GeV to 10 TeV published in Ref. 23. The gray band indicates the quadratic sum of statistical and systematic errors.

are consistent with AMS-02 but extend to higher energies by nearly one order of magnitude, showing a very smooth transition of the spectral index from -2.81 ± 0.03 (in the region 50–500 GeV) to -2.56 ± 0.04 (in 1–10 TeV), thereby confirming the existence of a spectral hardening and providing evidence of a deviation from a single power law by more than 3σ.

An update of CALET proton analysis, based on 5 years of data on the ISS, will be presented at the upcoming ICRC2021 conference together with preliminary results on the helium flux.

4.3. *The Spectra of Heavier Nuclei*

The observation of a spectral hardening in proton and helium, as well as in carbon and oxygen spectra,[18,20,22,25,26] have opened a new and unexpected scenario in CR phenomenology. In particular, the high statistics observations by AMS-02, up to a maximum detectable rigidity (MDR) of a few TV, clearly show that primary elements have a very similar rigidity dependence above ∼60 GV and that secondary elements (like Li, Be and B) also show a flux hardening, though with subtle differences that might be attributed to propagation effects (secondaries propagate first

as primaries and then as secondaries). Therefore, it is very important to extend the presently available measurements to the multi-TeV region and investigate the energy dependence of the spectral index for individual nuclear species with high accuracy. CALET is carrying out extensive measurements of the energy spectra, relative abundances and secondary-to-primary ratios of cosmic-ray nuclei.

Preliminary CALET results on the B/C ratio and on the spectra of heavier nuclei from neon to iron (Fig. 3) were previously reported (see for instance Refs. 4, 27, 28). In the following we will focus on the CALET published spectra of C, O and Fe.

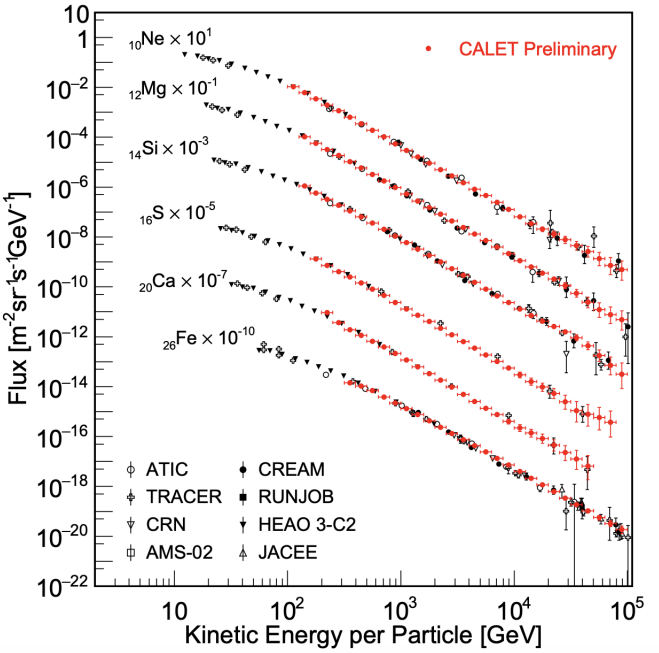

Fig. 3. Preliminary results of energy spectra of heavy primary components of Ne, Mg, Si, S, Ca and Fe as a function of energy par particle compared with previous observations. The Error bars of CALET data[28] represent the statistical uncertainty only.

4.4. *Carbon and Oxygen Spectra*

The energy spectra of carbon and oxygen and their flux ratio were measured by CALET in the energy range from 10 GeV/n to 2.2 TeV/n and published in Ref. 29. CALET observations (Fig. 4) allow to exclude a single power law spectrum for C and O at the level of more than 3σ. A spectral index increase (spectrum flattening) $\Delta\gamma = 0.166 \pm 0.042$ (carbon) and $\Delta\gamma = 0.158 \pm 0.053$ (oxygen) were measured above 200 GeV/n, respectively. The fluxes of C and O were found to share the same energy dependence with a constant C/O flux ratio 0.911 ± 0.006 above 25 GeV/n.

While the above results are consistent with the ones reported by AMS-02 for the same elements, the absolute normalization of CALET data is significantly lower than AMS-02, but in agreement with previous experiments (including PAMELA for carbon). For more details please refer to Ref. 29 and the Supplementary Material therein.

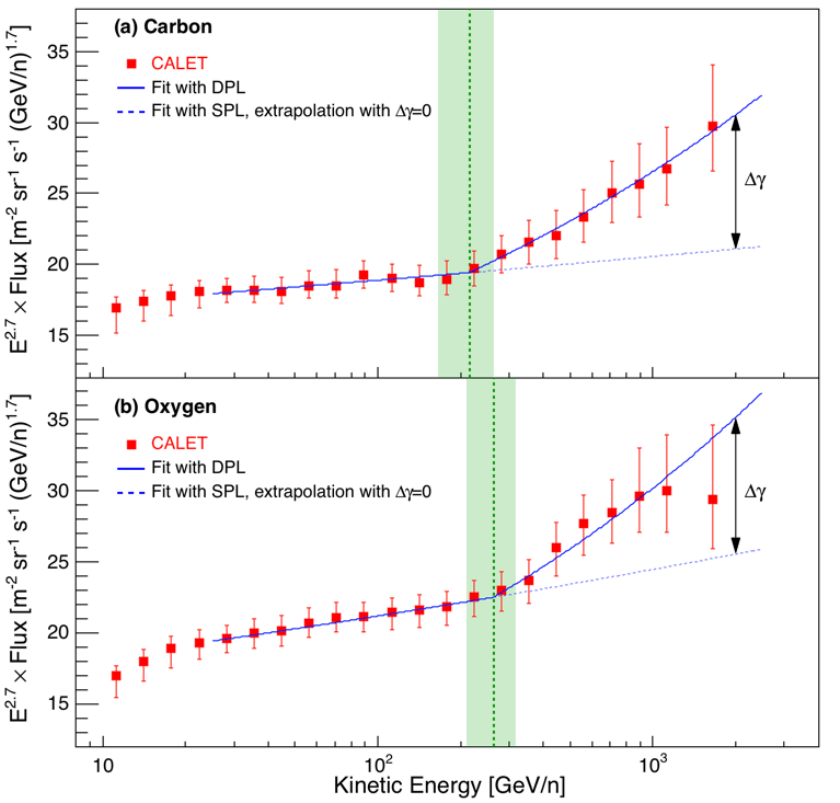

Fig. 4. Fit of the CALET (a) C and (b) O energy spectra[29] with a Double Power Law (DPL) function (blue line) in the energy range [25, 2000] GeV/n. The flux is multiplied by $E^{2.7}$ where E is the kinetic energy per nucleon. Error bars are the sum in quadrature of statistical and systematic uncertainties. The dashed blue lines represent the extrapolation of an Single Power Law function fitted to the data in the energy range [25, 200] GeV/n. $\Delta\gamma$ is the spectral index change above the transition energy E_0 (vertical green dashed line). The green band shows the uncertainty error on E_0 from the DPL fit.

4.5. *The Iron Spectrum*

In a recent paper,[30] the CALET collaboration reported their first measurement of the energy spectrum of cosmic-ray iron from 10 GeV/n to 2.0 TeV/n.

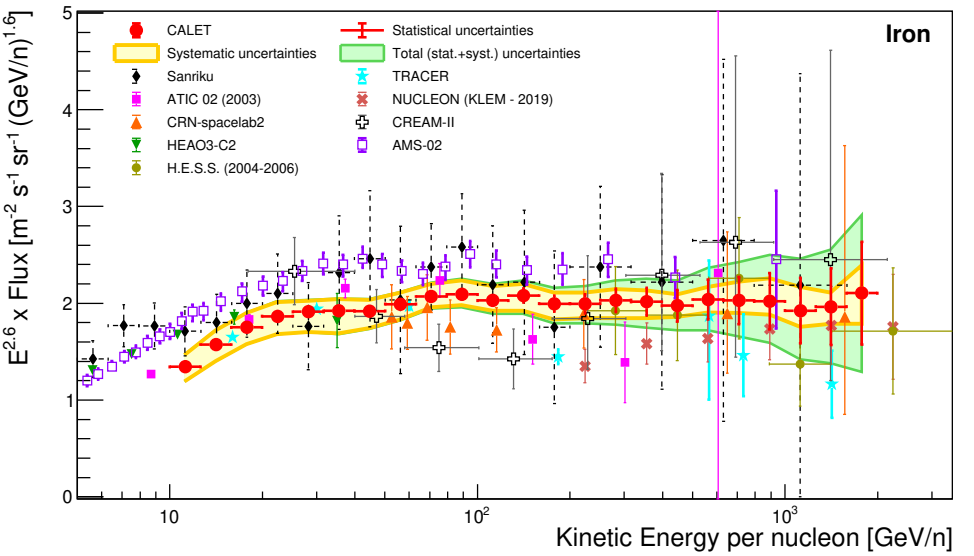

Fig. 5. CALET iron flux[30] as a function of kinetic energy per nucleon in GeV (with multiplicative factor $E^{2.6}$). The error bars of the CALET data (red filled circles) represent the statistical uncertainty only. The yellow band indicates the quadrature sum of systematic errors, while the green band indicates the quadrature sum of statistical and systematic errors. Also plotted are the data points from other direct measurements.[31–39]

The analysis is based on 4.4 years of observations and the measurement achieves a significantly better precision than most of the existing measurements of the same element. The CALET iron differential spectrum in kinetic energy per nucleon is shown in Fig. 5, where uncertainties including statistical and systematic errors are bounded within a green band. The spectrum is compared with the results from space-based (HEAO3-C2,[31] CRN,[32] AMS 02,[33] NUCLEON[34]) and balloon-borne experiments (ATIC-02,[35] TRACER,[36] CREAM-II,[37] Sanriku[38]), as well as ground-based observations (H.E.S.S.[39]). The CALET spectrum is consistent with ATIC 02 and TRACER at low energy and with CRN and HESS at high energy. CALET and NUCLEON iron spectra have similar shapes, while they differ in the absolute normalization of the flux. The latter turns out to be higher for CALET than for CRN by ∼10% on average, while it is lower by 14% with respect to Sanriku. CALET and AMS-02 iron spectra have a very similar shape (Fig. S12 of the Supplemental Material of Ref. 30), but differ in the absolute normalization of the flux by ∼ 20%.

Taking into account the average size of the large systematic errors reported in the literature, CALET data turn out to be consistent with previous measurements within the uncertainty error band, both in spectral shape and normalization. Below 50 GeV/n the spectral shape is found to be similar to the one observed for primaries

lighter than iron. Above the same energy, CALET observations are consistent with the hypothesis of an SPL spectrum up to 2 TeV/n, i.e., the flattening observed above a few hundred GeV/nucleon in the p-C-O spectra does not appear to be present in the iron spectrum in the sub-TeV region. Beyond this limit, the uncertainties given by the available statistics and large systematics do not allow yet to draw a significant conclusion on a possible deviation from a single power law. An SPL fit in this region yields a spectral index value $\gamma = -2.60 \pm 0.03$.

4.6. *The Observation of Gamma-Rays*

CALET can identify gamma-rays and measure their energies from ∼1 GeV to the TeV region. Both CHD and the first IMC layers are used in the offline analysis as anti-coincidence against incoming charged particles, taking advantage of the high granularity of the IMC.

Gamma-ray candidates are also required to deposit more energy in the bottom IMC layers than in the upper ones where pair conversion takes place. In addition to the HE trigger, CALET implements a LE-γ trigger extending the sensitivity to gamma rays with primary energies down to ∼1 GeV. This dedicated trigger is activated only at low geomagnetic latitudes (to avoid an increase of the dead-time) and it is also enabled whenever a gamma-ray burst is triggered by the Calet Gamma-Ray Burst Monitor (CGBM).[40] The first two years of data allowed a complete characterization of the performance of CALET as a gamma-ray instrument, the optimization of the event selection criteria, the determination of the effective area, Point Spread Function (PSF) and absolute pointing accuracy. Measured signals from gamma-ray bright point sources and diffuse galactic emission were found to be in agreement with simulated results and expectations from Fermi-LAT data.[41] The spectra from sources like Crab, Geminga, and Vela pulsars were measured by CALET and tested for consistency with parameterised LAT spectra. These results confirmed the sensitivity of the calorimeter in observing bright, persistent sources.[42] The gamma-ray sky observed by CALET using the LE-γ trigger is shown in Fig. 6.

CALET can also detect gamma-ray transients by means of the CGBM operating in the energy range of 7 keV–20 MeV. As of April 2021, 246 GRBs have been detected, 12% of which were classified as short, with an average rate of ∼44.6 /year.

A search for electromagnetic counterparts of gravitational waves (GW) triggered by LIGO/Virgo was performed with a combined analysis of the CGBM and the calorimeter. Candidate signals compatible with gamma-ray emission were searched for in time intervals of tens of seconds centered on the reported trigger times of GW151226, GW170104, GW170608, GW170814, and GW170817 events. No signal was detected for all GW events; upper limits on gamma-ray emission were set for GW151226 (CAL + CGBM) and GW170104 (CAL), while GW170608, GW170814, GW170817 turned out to be outside the CALET field-of-view.[43,44]

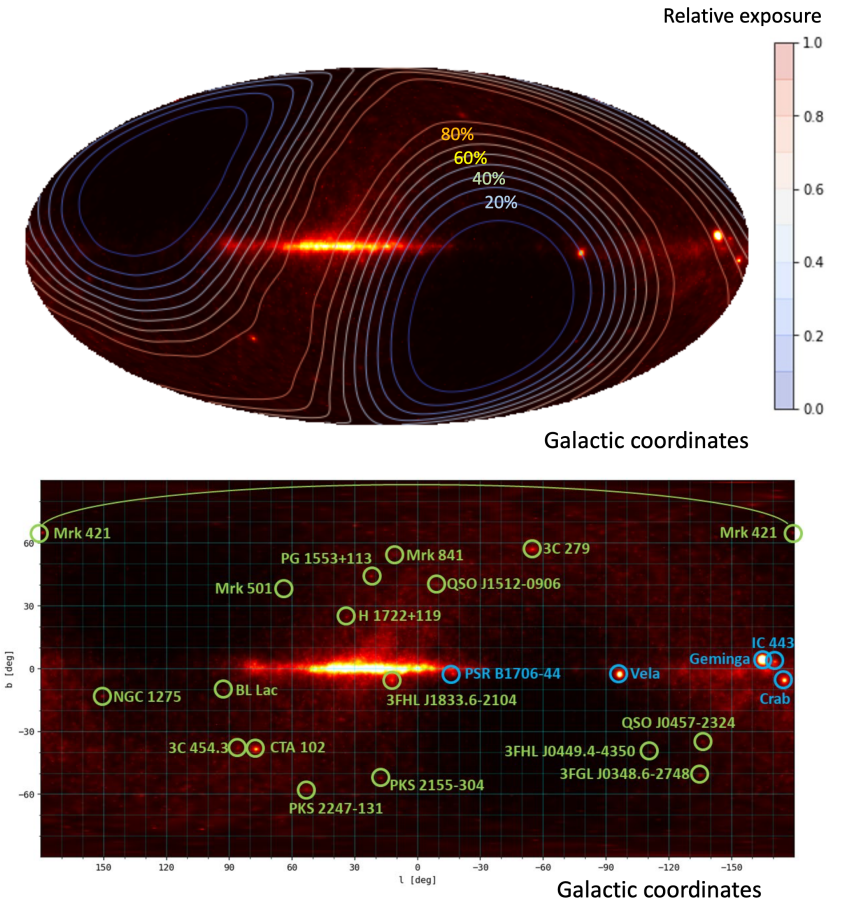

Fig. 6. Top: CALET gamma-ray sky map (observation period: 2015.11.01-2020.07.31) with the LE-γ trigger (E >1 GeV), shown in a Mollweide projection of galactic coordinates. White contours show the relative level of exposure compared to the maximum on the sky; bottom: point sources observed during the same period (with >1 GeV), including the Crab, Geminga, and Vela pulsars.

5. SUMMARY AND PERSPECTIVES

CALET was successfully launched on Aug. 19, 2015. The instrument performance has been very stable during all the scientific observation period from Oct. 13, 2015. CALET measurements of the electron spectrum were published in two papers,[9,11] the latter with improved statistics and extended energy range from 11 GeV to 4.8 TeV. The extension to five years of CALET on-orbit operations provided an increase of the available statistics in the electron observations by a factor $\sim$3 thereby contributing to a better understanding of the detector and of the systematic errors. A search for possible spectral footprints of nearby electron sources in the region above $\sim$1 TeV is in progress.

The wide dynamic range and excellent charge identification capability allow CALET to measure nuclei in cosmic rays from proton to iron and above, with an energy reach approaching the PeV scale. The proton spectrum was published up to 10 TeV (Ref. 23); C and O spectra to 2.2 TeV/n (Ref. 29), and Fe to 2.0 TeV/n (Ref. 30). The spectral index dependence on energy confirmed a spectral hardening for p, C, O with a smooth onset at a few hundred GeV. Measurements of the energy spectra and composition of all primary and secondary nuclei (and of their ratios) are ongoing. The relative abundance of the ultra heavy nuclei up to $Z = 40$ has also been preliminarily analyzed.[5]

The performance of the gamma-ray measurements has confirmed CALET's capability to observe the diffuse component and bright point-sources in the gamma-ray sky from ∼1 GeV to 100 GeV and above (Fig. 6). The continuous GeV gamma-ray sky observation with CALET complements the coverage by other missions and may help to identify unexplored high-energy emissions from future transient events. The latter phenomena are studied with the CGBM.

Follow-up observations were carried out in the X-ray and gamma-ray band of GW events during LIGO/Virgo observation campaigns.[43,44]

Solar modulation is constantly monitored and studied. Since the start of observations in 2015/10, a steady increase in the 1-10 GeV all-electron flux has been observed to present. In the past two years, the flux has reached the maximum flux observed with PAMELA during the previous solar minimum period.[45] Solar energetic particles (SEP) are also studied at high geomagnetic latitudes.

High statistics detection of MeV electrons originating from the radiation belt allows the study of relativistic electron precipitation.[46] This is one of the topics of Space Weather studies[47] which were added as additional observational targets for CALET after the start of on-orbit operations.

Important updates of CALET electron and proton analyses, as well as preliminary results on He, B, B/C analyses, will be presented at the upcoming ICRC2021 conference (highlights in Ref. 48).

The so far excellent performance of the instrument and the outstanding quality of the data suggest that a long-term strategy of CALET observations will contribute to a deeper understanding of cosmic-ray phenomena. CALET operations on the ISS have been recently approved for an extension to the end of 2024 (at least).

ACKNOWLEDGMENTS

We gratefully acknowledge JAXA's contributions to the development of CALET and to the operations aboard the JEM-EF on the International Space Station. We also wish to express our sincere gratitude to Agenzia Spaziale Italiana (ASI) and NASA for their support of the CALET project. This work was supported in part by JSPS Grant-in-Aid for Scientific Research (S) Number 26220708 and 19H05608, JSPS Grant-in-Aid for Scientific Research (B) Number 17H02901, JSPS Grant-in-Aid for Research Activity Start-up No.20K22352 and by the MEXT-Supported

Program for the Strategic Research Foundation at Private Universities (2011–2015) (No.S1101021) at Waseda University. The CALET effort in Italy is supported by ASI under agreement 2013-018-R.0 and its amendments. The CALET effort in the United States is supported by NASA through Grants No. NNX16AB99G, No. NNX16AC02G, and No. NNH14ZDA001N-APRA-0075.

Lecce, 73100, Italy
E-mail: paolo.bernardini@le.infn.it

DAMPE (DArk Matter Particle Explorer) is a satellite-born experiment promoted by the Chinese Academy of Sciences, with the collaboration of Italian and Swiss agencies. Since December 2015, DAMPE flies at the altitude of 500 km and collects data smoothly. The detector is made of four sub-detectors: top layers of plastic scintillators, a silicon-tungsten tracker, a BGO calorimeter (32 radiation lengths), and a bottom boron-doped scintillator to detect delayed neutrons. The main goal of the experiment is the search for indirect signals of Dark Matter in the electron and photon spectra with energies up to 10 TeV. Furthermore DAMPE studies cosmic charged and gamma radiation. Moreover, the calorimeter depth and the large acceptance allow to measure cosmic ray fluxes in the range from 20 GeV up to hundreds of TeV with unprecedented precision. An overview of the latest results about the charged cosmic rays will be presented.

Keywords: Cosmic rays; Satellite; DAMPE.

1. Introduction

The DArk Matter Particle Explorer (DAMPE) is a satellite-born experiment and it is funded by the strategic space projects of the Chinese Academy of Sciences with the active contribution of Italian and Swiss universities and institutions.[1,2] It is devoted to search for indirect dark matter signatures, to measure the fluxes of charged cosmic rays and to study the high energy gamma signal of astrophysical origin. In this paper the dark matter search and the gamma astronomy will be neglected to focus the reader's attention on the recent results about charged cosmic rays (electrons, protons and heavier nuclei).

2. The detector

The detector has been designed not only to reach the research goals. The final setup is an optimal compromise between scientific needs and reduction of power consumption and weight. In Fig. 1 the four sub-detectors of the DAMPE experiment are shown:

- PSD, in place of Plastic Scintillator strip Detector, used to measure the charge (Z) of incoming particles thanks to the Bethe-Bloch formula. The anti-coincidence with the PSD signal is also exploited to select gamma events.

- STK, in place of Silicon-Tungsten tracKer-converter, to reconstruct the trajectory of particles and to confirm the charge measurement. The tungsten is devoted to convert photons in electron-positron pairs.
- BGO, in place of bismuth germanate calorimeter (14 layers) of about 32 radiation lengths, that is ~ 1.6 nuclear interaction lengths, enough to get high resolution in energy measurement. The BGO bars allow to reconstruct the shower image in two views, then it is possible to distinguish between hadronic and electromagnetic ones.
- NUD, in place of NeUtron Detector, to further increase the hadronic shower rejection power.

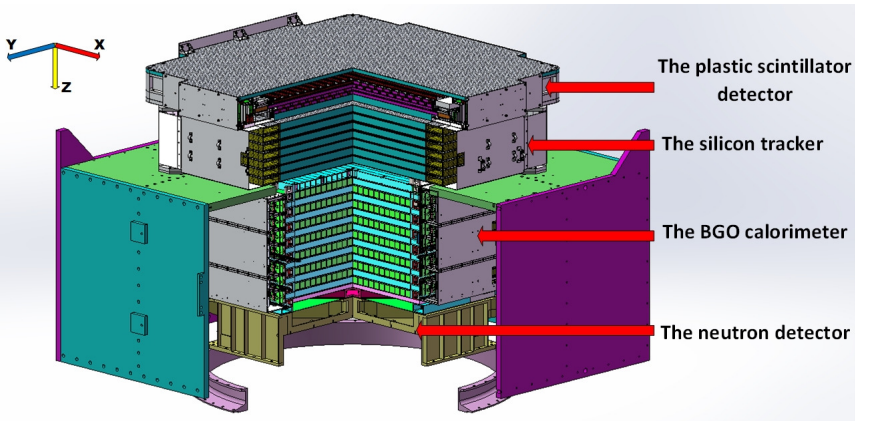

Fig. 1. The DAMPE detector with its 4 sub-detectors.

DAMPE performances were verified by a series of beam tests at CERN.[1,3,4] The wide energy range of electron beam and the high purity of proton beam allowed to check energy resolution, linearity (Fig. 2, left) and e/p separation (see Fig. 7 in the following). Also beams of argon and lead fragments were used to check the PSD capability to measure Z for heavy ions (Fig. 2, right for the argon beam). Furthermore sea-level muon test have been performed during different stages of the DAMPE assembly. Then the energy response to Minimum Ionizing Particles (MIPs), the efficiency and the detector alignment have been checked with a large sample of atmospheric muon tracks.

3. In-flight DAMPE performances

The satellite has been successfully launched on December 17, 2015. After few days all detectors were powered on and the data acquisition began very soon. We would like to stress that the detector works properly and flies at the altitude of 500 km on a Sun-synchronous orbit since almost 6 years, in spite of its foreseen 3-years life.

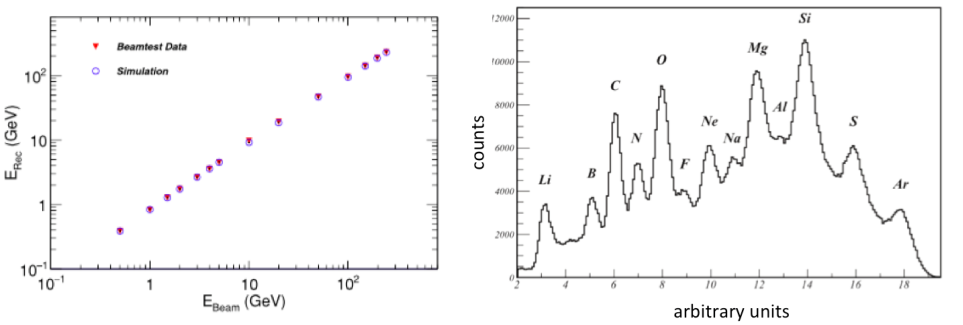

Fig. 2. Beam test - Left panel: Reconstructed energy versus electron beam energy (simulated and beam-test data are shown). Right panel: PSD charge spectrum of fragments of an argon beam (helium peak has been removed).

On orbit the detector is calibrated by using the standard scientific data and dedicated calibration data. The data acquisition system runs continuously in observation mode for most of the time and switches to calibration mode for 40 seconds twice per orbit. All the calibration results (pedestal values, dynode ratios, energy gains, trigger thresholds and so on) are consistent with the ground ones and very stable after temperature correction. The STK alignment allows a significant improvement of the tracking resolution.[5] In Fig. 3 (left panel) the PSD signal due to MIP protons is plotted as a function of time in a period of about 4 months. A similar plot is shown in the right panel of Fig. 3 for BGO signal due to no-showering helium nuclei. The high stability of the detectors is confirmed by these and many other checks.

4. Cosmic Rays (CR)

After more than 100 years since the CR discovery many questions are yet without answer. The spectra before the knee do not fit perfectly with a simple power-law and the canonical model of CR acceleration in Super Nova shock does not explain the observed structures. Precise measurements for different chemical components are essential for testing the CR models (sources, production, acceleration, diffusion in the galaxy, presence of different populations, and so on).

DAMPE can contribute to CR studies measuring the spectrum structures for different nuclei in the range from tens of GeV up to hundreds of TeV. The possibility to reach such high energies with on-orbit detectors put a bridge between space and ground experiments and pave the way to a combined analysis.

The measurement of CR spectra is based on the estimate of charge and energy of incoming particles. By means of the STK tracking (supported also by the information on the fired BGO bars) the path-length in PSD is reconstructed. Then the PSD signal allows to measure the charge (square root of the energy release in PSD is proportional to path-length and Z). In Fig. 4 the elemental CR spectrum is

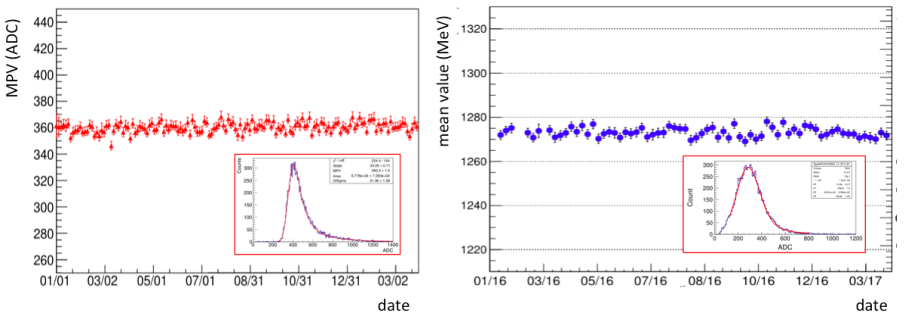

Fig. 3. Left panel: the deposited energy in PSD for minimum ionizing protons is fitted with the convolution of a Landau function with a Gaussian one (insert). The Most Probable Value (MPV) is shown as a function of time. Right panel: similar plot for minimum ionizing helium nuclei in BGO (the mean value of the deposited energy is displayed versus time instead of MPV).

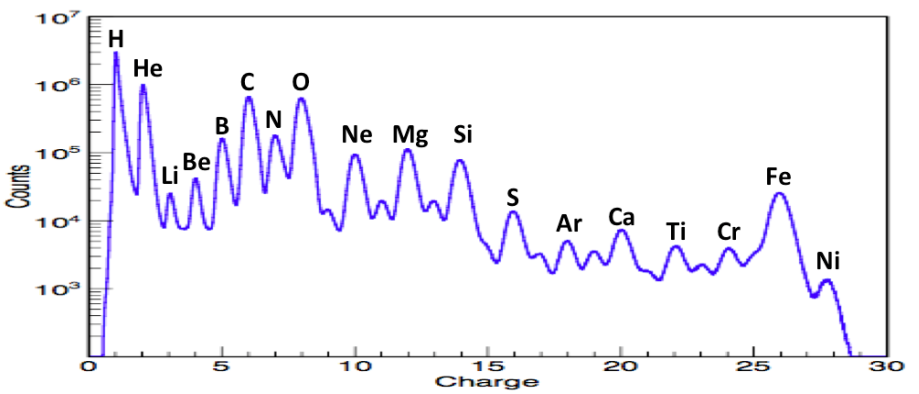

Fig. 4. Charge spectrum reconstructed on the basis of the deposited energy in the PSD. Almost all Z-peaks are visible up to nickel.

shown from hydrogen up to iron and beyond. By means of the template-fit procedure the different peaks are separated and the mutual contamination is estimated (an example is shown in Fig. 5 where the data-Montecarlo agreement is excellent).

Lastly the energy is estimated by the signal in the BGO calorimeter. Its unprecedented thickness allows to push the direct measurement of CR spectra to highest energies. The imaging allows also to distinguish the features of hadronic showers from electromagnetic ones.

The DAMPE spectra for protons[6] and helium nuclei[7] are presented in Fig. 6. The analyses for heavier nuclei are in progress. Both the spectra in Fig. 6 show a similar shape inconsistent with a single power-law. The fit of these spectra improves significantly using smoothly-broken power-laws in order to reproduce a hardening followed by a softening. The observation of the hardening confirms previous measurements, instead the softening is observed for the first time by DAMPE with such

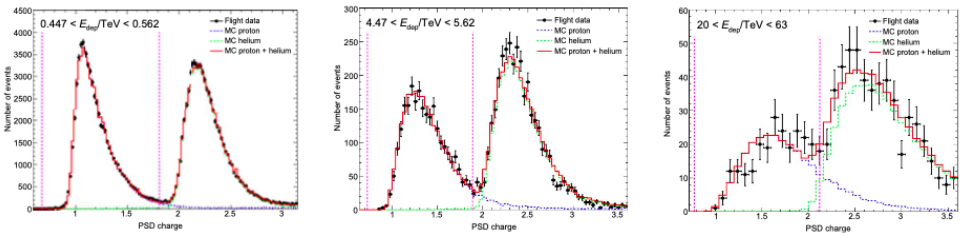

Fig. 5. Combined PSD signal for protons and helium nuclei, for different ranges of BGO energy (447-562 GeV, 4.47-5.62 TeV, 20-63 TeV). The colour codes to distinguish on-orbit and simulated data are shown in the plot. The cut used to select proton candidates is represented by the vertical dotted lines.

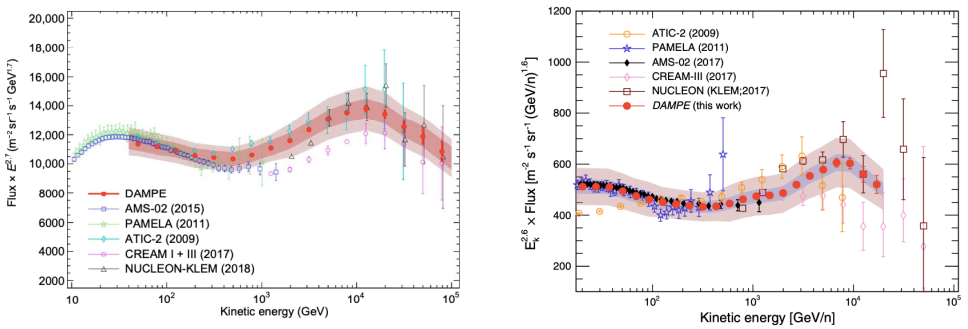

Fig. 6. Spectra for cosmic protons (left panel) and helium nuclei (right panel). For protons (helium) the flux is multiplied for $E^{2.7}$ ($E^{2.6}$). Two changes of spectral index are visible in both the spectra (hardening followed by softening).

significance. The break-energy for the softening suggests a dependence on particle charge, although a dependence on mass can not be ruled out yet.

5. Cosmic electrons and positrons (CRE)

Some measurements[8–14] reported an unexpected structure of CRE flux. Furthermore evidence for a spectral break in the TeV range of the CRE flux has been provided by indirect measurements[15,16] affected by significant uncertainties.

In two years of data taking DAMPE measured CRE spectrum in the range from 25 GeV to 4.6 TeV[17] with very low background. Indeed the imaging properties of the BGO calorimeter are exploited to recognise the showers initiated by CRE. The PID algorithm is based on the spread of the BGO hits (*spread*) and on the fraction ($F_{\rm last}$) of energy on the lower layer with respect to the sum of energies released on all the BGO layers. The quantities *spread* and $F_{\rm last}$ are combined in the parameter

$$\zeta = F_{\rm last}\ \frac{(spread/\mathrm{mm})^4}{8\times 10^6}. \qquad (1)$$

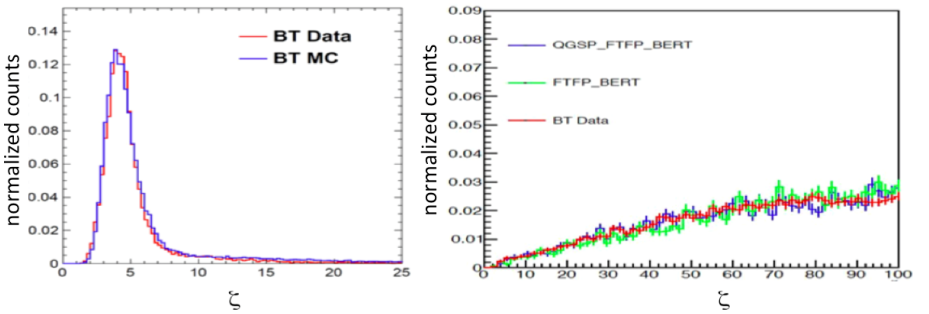

Fig. 7. Beam test (BT) - The ζ-distributions for electrons (left panel) and for protons (right panel). In the proton plot the real data are compared with simulations based on different models of the hadronic interactions.

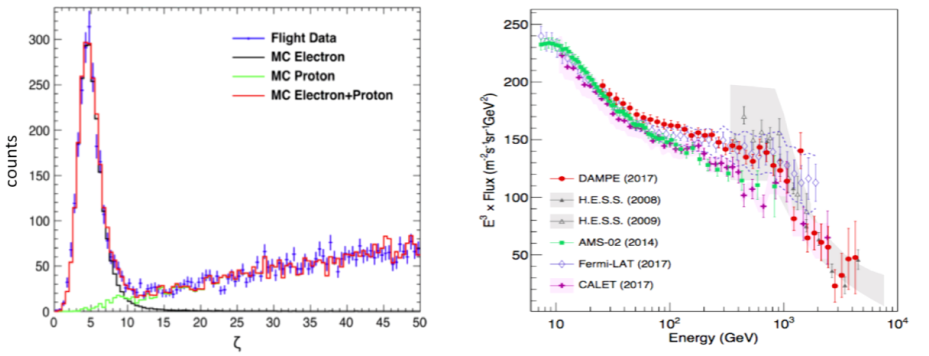

Fig. 8. Left: Distribution of the ζ parameter (the cut $\zeta < 8.5$ is applied to select the CRE sample). Right: electron and positron spectrum measured by different experiments (DAMPE: red dots, HESS systematic errors: grey band).

The efficiency of the ζ-parameter in order to distinguish electrons and protons has been verified in the beam test (Fig. 7). Then the CRE sample is selected by requiring $\zeta < 8.5$ (see Fig. 8, left panel). The CRE flux measured by DAMPE as a function of energy is shown in right panel of Fig. 8 with measurements of others experiments. Also in this case a smoothly broken power-law is preferred to fit the largest part of the spectrum.

6. Conclusions

The DAMPE detector works extremely properly since its launch more than 5 years ago and it is expected to operate stably in the next few years. Many analyses based on DAMPE data are going on successfully. The measurements of CRE, proton and helium spectra are particularly remarkable. Indeed the direct detection of spectral breaks confirms previous direct and indirect measurements, clarifies the shape of

the spectra at highest energies. These results put severe constraints about models of acceleration and diffusion of galactic cosmic rays. Many new results are expected from the analysis of the complete sample of DAMPE data.

The Pierre Auger Observatory has by now achieved an exposure of order 10^5 km^2 sr yr, exploring about 85% of the sky. In this talk, I will review some of the recent results, including the detailed measurements of the features in the cosmic ray spectrum, the study of the anisotropies in the cosmic ray arrival directions both at large and intermediate angular scales, the inferred mass composition, and multimessenger searches.

Keywords: Cosmic rays

The Pierre Auger Observatory has been operational since January 2004 and has by now reached an accumulated exposure of order 10^5 km^2 yr sr (see Fig. 1). This enormous increase in the number of detected cosmic rays (CRs) with ultrahigh energies, by more than an order of magnitude with respect to previous observations, has allowed measuring the CR spectrum with unprecedented detail,[1] firmly establishing the suppression at the highest energies, above 47 EeV, as well as the various features of the spectrum, including the discovery of a softening at 14 EeV, the observation of the ankle at 5 EeV, the second-knee at 0.16 EeV, and the low-energy ankle at 28 PeV (see Fig. 2).

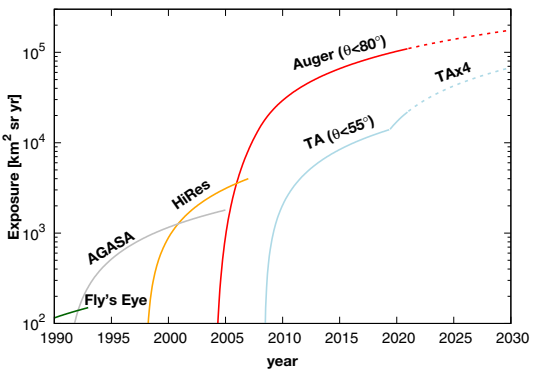

Fig. 1. Exposure vs. time of ultrahigh-energy air shower arrays. The previous experiments (Fly's Eye, HiRes and AGASA) as well as the Auger and Telescope Array exposures used in anisotropy searches at the highest energies are shown, together with the extrapolations to the next years involving the enlarged TAx4 upgrade.

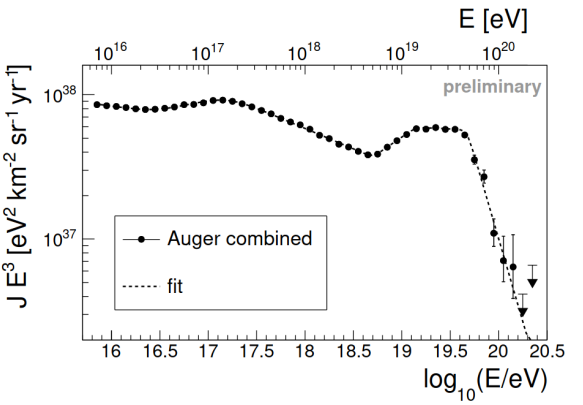

Fig. 2. Combined spectrum from measurements obtained with different techniques together with a broken power-law fit (see ref.1 for details).

By observing events with zenith angles up to 80°, i.e., covering 85% of the sky, it also became possible to determine with high significance an anisotropy in the CR arrival direction distribution at energies above 8 EeV, which has a characteristic dipolar pattern with an amplitude of about 7%.[2] The direction of this anisotropy, with the reconstructed dipole pointing about 115° away from the direction towards the Galactic center, provides a clear indication supporting the extragalactic origin of the CRs at these energies (see left panel of Fig. 3). Considering several energy bins above 8 EeV, the dipole amplitude is found to actually increase with energy, and the direction of the fitted dipole in all bins lies not far from the direction of the outer spiral arm of the Galaxy.[3] At energies below 8 EeV, no significant anisotropies were observed, so that relevant upper bounds on the equatorial dipole amplitudes were set down to energies of 0.03 EeV, and interestingly the right ascension phase of the flux modulations below about 1 EeV is not far from the right ascension of the Galactic center.[4] Hints of anisotropies at intermediate angular scales, of order 20°, have been obtained at energies above about 40 EeV, with the main excess lying around the direction towards the nearby radiogalaxy Centaurus A (right panel of Fig. 3). This radiogalaxy then provides a possible candidate source of ultrahigh-energy CRs, although other potential CR sources are also located in the same region of the sky, such as the starburst galaxies NGC4945 and M83. A likelihood ratio test comparing the CR arrival directions above different threshold energies with a catalog of nearby starburst galaxies, flux-weighted and smeared, reveals a maximum significance above a threshold of 38 EeV for an angular scale of a top-hat window of 25°.[5]

The hybrid nature of the Auger Observatory, with both surface detectors (SD) and fluorescence detectors (FD), allows it to perform sensitive measurements of the mass composition of the primary CRs. The SD consists of instrumented water tanks that measure the Cherenkov light emitted by relativistic secondary charged particles

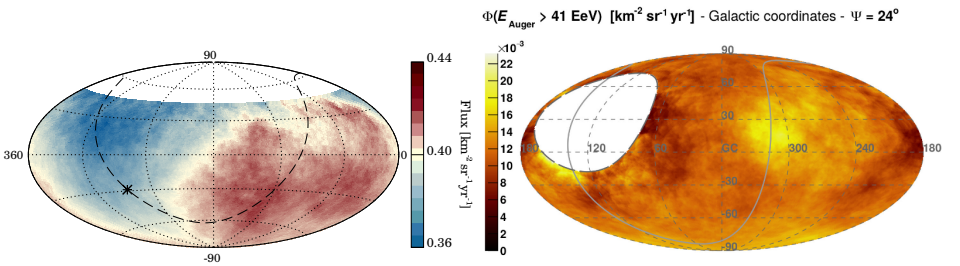

Fig. 3. CR flux map above 8 EeV averaged on windows of 45° radius (left panel, in Equatorial coordinates) and above 41 EeV averaged of 24° radius windows (right panel, Galactic coordinates).

crossing them and is hence sensitive to both the muonic and the electromagnetic components of the showers reaching ground level. The FD telescopes measure instead the longitudinal development in the atmosphere of the CR induced showers by observing, with a $\sim 15\%$ duty cycle, the light emitted by the N_2 air molecules that get excited by the passage of the electromagnetic component of the shower. The FD allows for an almost calorimetric measurement of the primary energy, which is also used to calibrate the SD energy assignment. Moreover, the atmospheric depth at which the showers reach their maximum development, $X_{\rm max}$, provides crucial information about the mass composition of the CRs, because lighter primaries give rise to more penetrating showers than heavier ones since these last can be considered as a superposition of many lower energy showers induced by the individual nucleons. The measurements of the distribution of $X_{\rm max}$ values allowed us to establish[6] that at energies of a few EeV the average CR masses are light, being dominated by H and He primaries, and they become increasingly heavier as the energy is further increased, lying in the ballpark of the expectations from primary N nuclei at energies of 30 EeV and possibly even heavier at higher energies (the actual masses inferred depend, however, on the hadronic interaction model adopted in the analysis). The narrow spread in the fluctuations on the values of $X_{\rm max}$ measured above the ankle energy also implies that there is little admixture between elements with disparate masses at these energies. These measurements are depicted in Fig. 4.

A combined fit to the spectrum and anisotropy measurements within an astrophysical scenario with equal luminosity sources having power-law spectra with rigidity dependent cutoffs has been performed in ref. 7.

Besides the measurement of $X_{\rm max}$ with FD, also the SD has been used to obtain composition information,[8] exploiting the rise-times of the measured signals in the triggered detectors. Given that the shower muons travel straight from their production points high in the atmosphere, while the electromagnetic component of photons, electrons, and positrons have a more diffusive propagation in the atmosphere, the muonic signal is expected to be more concentrated in the early part of the shower front while the electromagnetic one will have a larger spread. Hence, shorter rise times are expected in the signals from showers with a more abundant

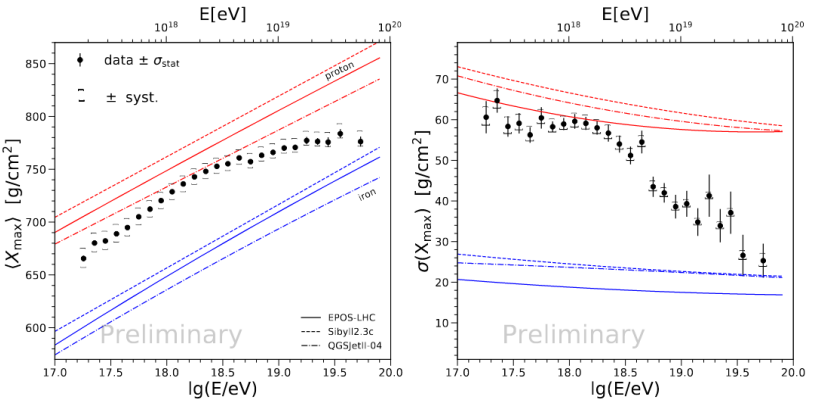

Fig. 4. Mean $X_{\max}$ and its dispersion as a function of energy, as measured with the Auger fluorescence detectors.

muonic component, as is the case for the showers induced by heavier nuclei. These measurements can then be correlated with the FD measurements of the depth of shower maxima. Given the larger statistics obtained with SD, which has a 100% duty cycle, it has become possible to obtain more detailed information about the composition at the highest energies, actually splitting the highest energy FD bin in four SD bins. In this way the trend towards a heavier composition for increasing masses is confirmed with SD up to the highest energies.

Another search performed has been to look for a component of photon-induced showers, which would be very poor in muons, and this allowed to set stringent bounds on the primary photon fluxes above EeV energies.[9] The upper bounds strongly disfavor exotic scenarios for the production of UHECRs, such as those involving superheavy particle decays (see left panel in Fig. 5).

Also ultrahigh-energy neutrinos have been searched through the study of inclined showers.[10] Very inclined showers produced by ordinary nuclear-induced cascades, which initiate high in the atmosphere, would have their electromagnetic component totally attenuated by the time they reach ground level. On the other hand, neutrino-induced showers can be initiated at any depth in the atmosphere, and those originating close to the detector will have a significant electromagnetic component, looking then 'younger' than the hadronic ones, what could be exploited to single them out from the background. Actually, the most sensitive neutrino search is that looking for showers produced by Earth-skimming tau neutrinos interacting in the crust of the Earth and producing tau leptons that manage to exit from the soil before decaying to produce the atmospheric shower that may be observed. The most sensitive energy range for these searches is around the EeV, which just happens to be the range where the fluxes of cosmogenic neutrinos are expected to peak. In particular, cosmogenic neutrinos could arise from the photo-pion production taking place when CR protons with energies exceeding the GZK threshold of about 40 EeV

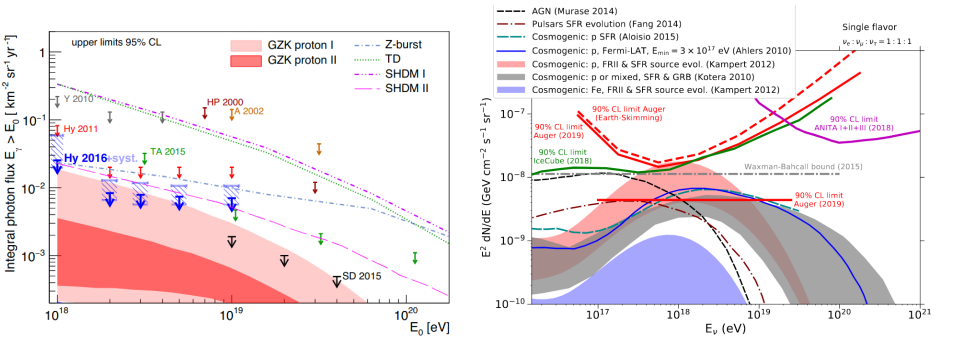

Fig. 5. Bounds on photon fluxes (left) and neutrino fluxes (right), compared to some model expectations.

interact with CMB photons, and the neutrinos produced in the charged pion decays have typical energies of about $E_p/20$. No neutrino candidates have yet been observed in these searches, allowing us to set bounds that start to constrain some of the most optimistic scenarios for the production of cosmogenic neutrinos, which are those with protons dominating the CR fluxes at the highest energies. However, more realistic scenarios with a predominantly heavier composition at the highest energies predict fluxes below the present bounds (see right panel of Fig. 5).

Searches of neutrinos in association with the first neutron star binary merger detected by the LIGO-Virgo Collaboration also led to negative results,[11] in spite of the lucky coincidence that the event just happened to be a few degrees below the horizon, a situation in which the sensitivity to Earth-skimming tau neutrinos is largely enhanced. It is interesting to note that the model predictions for the case in which the jet of this closeby merger had been aligned with the line of sight were not very far from the Auger sensitivity, but the lack of an observed signal is not unexpected, given the slight misalignment of the jet in this particular merger. Also searches in the direction towards the blazar TXS 0506+056, from which a $\sim$ 300 TeV neutrino was observed by IceCube, revealed no neutrino candidate, allowing to constrain the neutrino flux from this object at the highest energies.[12]

The Pierre Auger Observatory is at present undergoing an upgrade, consisting in adding 4 m^2 scintillators on top of each SD and using faster electronics, which in combination with the water-Cherenkov detectors should allow for a cleaner separation between the electromagnetic and muonic components of the showers. This separation should make it possible to obtain composition information on an event by event basis with the SD detector, allowing, for instance, to improve the sensitivity of the anisotropy studies by restricting them to just the lighter CR component (which is less deflected by the Galactic and extragalactic magnetic fields). Also radio antennas are being added to each SD detector to observe the radio emission from the electromagnetic component of the showers, which should help in particular to study the composition of the inclined showers. This new phase of the Observatory

should allow for improved studies of all the topics just discussed, as well as to better handle the still remaining open issues.

The HERD space mission

F.C.T. Barbato on behalf of the HERD Collaboration

Gran Sasso Science Institute, L'Aquila, Italy
INFN Laboratori Nazionali del Gran Sasso, Assergi, L'Aquila, Italy
E-mail: felicia.barbato@gssi.it

The High Energy cosmic-Radiation Detection (HERD) space mission is now being designed, as a result of an international collaboration among several chinese and european institutions, to make cosmic ray (CR) direct measurements at the highest possible energies with current technologies.

HERD primary scientific goals include precise measurements of the energy spectra of CR individual species up to few PeV, reaching the knee of the all-particle spectrum, and study electrons and photon of spectra from GeV up to tens of TeV, also contributing to multimessenger observations together with other satellites and ground-based experiments.

In order to reach these goals HERD is configured to accept incident particles from its top and the four lateral sides. The baseline design includes covering the top and fours sides with: the Silicon Charge Detector (SCD), for incident particle trajectory and charge measurement, the Plastic Scintil- lator Detector (PSD), for photon tagging and precise charge measurement, and a scintillating Fiber Tracker (FIT). The core of the facility is made by a LYSO crystal calorimeter (CALO) that with its 3 interaction lengths and 55 radiation lengths will allow the measurement of incident gamma-rays, electrons and cosmic ray nuclei with unprecedented resolution and 3D reconstruction. In addition, on one side a Transition Radiation detector (TRD) will be installed for on-orbit calibration of the CALO.

Keywords: Cosmic rays; Chinese Space Station; space missions; SiPM; LYSO.

1. Introduction

Cosmic rays are messengers with which we use to explore the Universe and its laws. Despite being discovered more than one century ago, our knowledge about them is still limited. In the recent years, some progresses have been made in our knowledge and understanding of them thanks to several experiments. Nevertheless, many fundamental questions on this topic are still open: where are they produced? how are they accelerated to such energies? how do they propagate in the Universe?

A big issue concerns the so-called *knee* region of the primary cosmic ray spectrum. Here (at $\sim$ PeV energies), the spectrum steepens. This behaviour was firstly observed in 1958, nevertheless the cause remains still unknown. Because of the rapidly falling intensity of the cosmic ray flux with energy, in order to explore this region we need experiments with a large acceptance and operating over years. In past this role was played by ground based experiments. Nevertheless, this kind of experiments are not able to perform mass composition studies. For this reason, we need new spaceborne observatories performing studies aiming at finding an answer to this question.

The High Energy cosmic Radiation Detection (HERD) facility is an international space mission that will start operation around 2027 to make cosmic ray direct measurements at the highest possible energies with advanced technologies. It will be installed on the Chinese Space Station (CSS) where it will observe the high energy sky for more than 10 years. The HERD project involves researchers from Chinese institutions, Italy, Switzerland and Spain. The unprecedented acceptance and the 3D segmented calorimeter allow HERD to represent the future of the direct cosmic ray detection and a missing observational link among space-based and ground-based experiments.

2. Scientific objectives

HERD primary scientific goals include:

- extending the measurement of cosmic ray flux up to a few PeV testing the theory of the knee structure as due to galactic source acceleration limit;
- extending the measurement of $e^+ + e^-$ flux up to several tens of TeV testing the hypothesis of the expected cutoff at high energy distinguishing between DM or astrophysical origin of positron excess and looking for possible other structures of the spectra and eventual anisotropies;
- large acceptance, high sensitivity to γ-rays up to several hundreds of GeV for a long term gamma ray sky also searching for γ-lines associated to DM annihilation, while accomplishing a γ-ray sky survey up to very high energy.

Cosmic ray origins Since their discovery in 1910, our knowledge about cosmic ray physics experienced several progresses. Today, we are in another golden era for cosmic rays, due mainly to their connection with physics at the highest energy, indirect search for particle dark matter and site and mechanism of cosmic accelerators. Information about the latter topic can be obtained from the energy spectrum of cosmic rays. It is expected to follow a power-law for energies below the "knee" (at 3-4 PeV) because of the canonical shock acceleration of particles, see FIG. 1.

Nevertheless, several experiments observed changes in the power-law spectral indices for protons, helium, and heavy nuclei. Current data suggest a hardening of the spectra above about 0.2 TeV/nucleon. The hardening at energies above 200-400 GeV is well established since the first observation by PAMELA,[2] while the softening at energies above 10 TeV is observed by different experiments with the first strong evidence in DAMPE data.[3] The deviations from single power law of the spectra motivate extensive investigations for deeper understanding of the acceleration and propagation mechanisms or of new possible cosmic ray sources. Several theoretical solutions have been proposed, exploiting different hypotheses on source properties/populations, acceleration/propagation mechanisms and particle physics issues at high energies, in order to give a satisfactory explanation of this behaviour.[4]

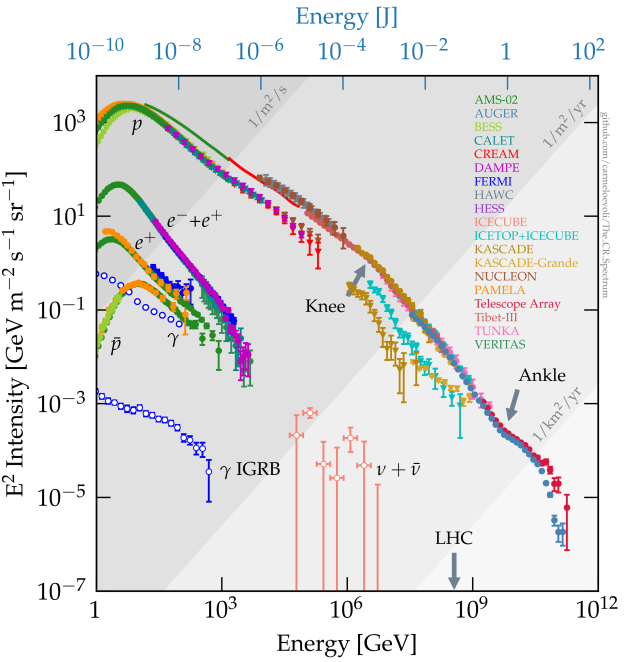

Fig. 1. Up-to-date summary of measurements of CR energy spectra.[1] For energies below ~ 100 TeV, the spectra of different species are shown, and for higher energies the all-particle spectra are plotted. References of data: CREAM; ATIC; AMS-02; PAMELA; Fermi-LAT; HESS; IceCube; Akeno; Tibet; AGASA; HiRes; Auger.

So one of the HERD objectives will be the extension of the measurement of p and He flux up to a few PeV. The HERD data can clearly reveal the knee structure of both protons and Helium nuclei and can critically address the possible Z-dependence, A-dependence, or constant knee of different compositions, which are very important to understand the physical nature of the knee of CRs, see FIG. 2. Measurements of secondary over primary ratio, such as B/C, are important to probe the propagation of CRs. HERD will extend the precise measurements of B/C up to a few TeV/nucleon, thus accurately determine the propagation behaviour of CRs.

Finally, taking into account that the Iron nuclei are the end-products of stellar nucleosynthesis, they are thus very good tracer of the acceleration sites of CRs. HERD is expected to strongly improve such measurements.

Measurement of cosmic electron+positron spectrum and Dark Matter signal search In 2009, PAMELA experiment reported a positron excess[5] in the CR flux at energies 10-100 GeV, later it was very precisely measured by AMS-02 in an extended energy range up to 700 GeV.[6] Such a signal is generally expected from dark matter annihilation. However, the hard positron spectrum and large amplitude are difficult to achieve in most conventional WIMP models. A variety of theoretical

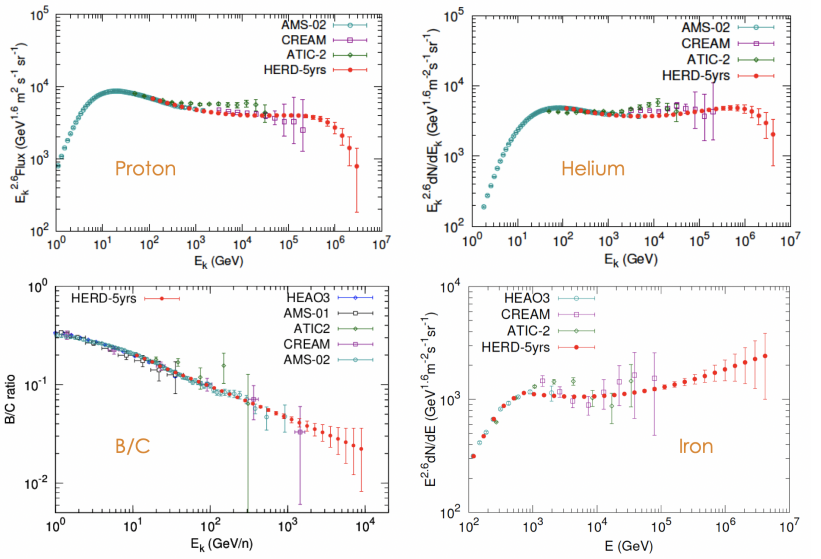

Fig. 2. Expected p, He, B/C and Fe energy spectra measured with 5yr exposure of HERD, compared with that observed by other experiments.

studies focusing on the DM interpretation of this excess have been performed in the literature, however the origin of these high energy positrons remains debatable.

Evidently, it is of a great importance to extend this measurement with greater precision at higher energy scales in order to distinguish the origin of the high energy electrons/positrons, either from DM annihilation or from astrophysical sources.

In this sense, progress has been made by the satellite experiment DAMPE (launched in 2015) which in 2017 reported its first result of CR electrons/positrons, showing a cutoff at ~ 0.9 TeV.[7] It has long been believed that the shape of the spectral cutoff is different for the astrophysical source (softer) and DM annihilation (harder).

Compared with DAMPE, the HERD experiment will have a larger acceptance and can extend the measurement of the electron-positron spectrum to higher energies with optimal precision, see FIG. 3, thus providing valuable insight on high energy astrophysics and DM studies.

A high energy gamma ray observatory HERD will be the most sensitive sky surveyer with very wide field of view for gamma rays between tens of GeV and several TeV, thus extending the Fermi-LAT observations at higher energies (E>300 GeV) and additionally complementing CTA, the most sensitive high energy γ-ray telescope with a narrow field of view.

The observation of the γ-ray sky is among the main scientific objectives of the HERD collaboration being relevant in understanding the nature of DM while also studying cosmic ray acceleration and propagation mechanisms in the Galaxy.[8]

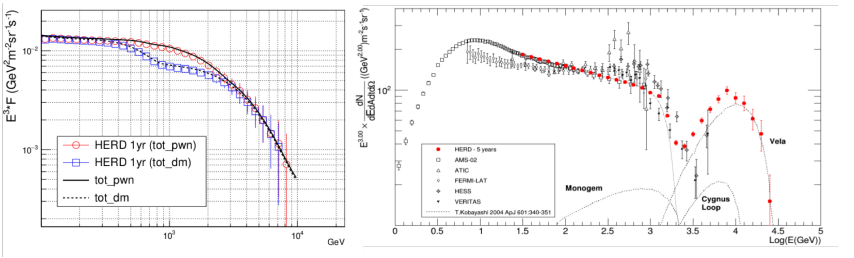

Fig. 3. Expected $e^+ + e^-$ flux in 1 year with PWN or DM sources on the left. Expected e++e- flux in 5 years on the right.

Information about cosmic ray spectra and intensities in distant locations, indeed, could be extracted by measuring the diffuse γ-ray emission, that traces energetic particle interactions, primarily protons and electrons, in the Interstellar Medium (ISM).[9] Moreover, the understanding of Galactic diffuse emission is also crucial to dark matter studies, since γ-rays can be produced in cosmic ray interactions mainly via decay of neutral pions and possibly from the annihilation of dark matter weakly interacting massive particles (WIMPs). The Galactic Center (GC) is expected to be the brightest source of DM annihilations in the γ-ray sky by several orders of magnitude. Although due to several astrophysical processes in the crowded GC region make it extremely difficult to disentangle the DM signal from conventional emissions, the DM-induced γ-ray emission is expected to be so large there that its search is of crucial relevance.[10] In the analyses of Fermi data of the Galactic center, the diffuse γ-ray backgrounds and discrete sources, as we model them today, seem to account for the majority of the detected γ-ray emission. Nevertheless, residual emission not accounted for by the above mentioned models of standard sources could still be present,[11][12] and be interpreted as product of DM annihilation.[13] The spectrum and spatial distribution of the GeV excess is consistent with what can be expected from Weakly Interacting Massive Particle (WIMP) with mass of a few tens of GeV of annihilating to standard model particles in the inner Galactic halo. With significantly improved sensitivity, HERD could measure with high resolution these spectra. Furthermore, the higher effective area especially at TeV energies may help in extending the energy range in which we detect the Galactic diffuse emission. This would provide a unique bridge for ground-based experiments sensitive in the TeV energy range.

3. The HERD payload

The HERD payload will be installed onboard of the CSS around 2027 and will be operating for 5 to 10 years, see TAB 1. Its heart, the calorimeter (CALO), will be surrounded on 5 sides by the other subdetectors i.e. the Fiber Tracker (FIT), the Plastic Scintillator Detector (PSD) and the Silicon Charge Detector (SCD), while a Transition Radiation Detector (TRD) will be placed only on one lateral side,

see FIG. 4. This configuration will guarantee a wide field of view and more than one order of magnitude increase in acceptance with respect to current experiments, see TAB 2.

Table 1. Mission requirements of the HERD payload

Mission requirements	Value
Life Time	>10 years
Orbit	Circular LEO
Altitude	340-450 km
Inclination	42°
FOV	± 70 °
Mass	4t

Table 2. Main requirements of the HERD payload

Item	Value
Energy range (e/γ)	10 GeV - 100 TeV; >0.1 GeV(γ)
Energy range (nucleus)	30 GeV - 3 PeV
Angular resolution (e/γ)	0.1 deg.@10 GeV
Charge measurement (nucleus)	0.05 - 0.15 c.u.
Energy resolution (e)	1% @ 200 GeV
Energy resolution (p)	20% @ 100 GeV - PeV
e/p separation	$\sim 10^{-6}$
Geometric factor (e)	>3 m^2Sr @ 200 GeV
Geometric factor (p)	>2 m^2Sr @ 100 GeV

The Silicon Charge Detector The silicon charge detector is the outermost shell of HERD. It will measure the incident particle trajectory and charge of cosmic rays up to Z=26. Its position is chosen to ensure a reliable charge measurement and to avoid fragmentation phenomena of high energy particles. The current design follows the example of the DAMPE Silicon Tracker (STK). Each detection unit, i.e. each side, contains 8 layers of 300 μm microstrip silicon detectors mounted with alternating orthogonal direction strip directions onto low-density aluminum honeycombs, see FIG. 5. It is highly segmented to minimize the backscattered secondary particles coming from the CALO. The global active area is about 60 m^2.

We simulated several samples of proton, helium, carbon, oxygen, silicon, and iron nuclei with energies from 10 GeV/n to 1 TeV/n and with isotropic incidence to study the performances of the SCD. We found that the combined charge resolution of 8 layers is below 0.3 c.u. for all samples. Test beams are ongoing at the CERN SPS and PS ion beam lines to directly measure charge resolution of SCD prototypes.

The Plastic Scintillator Detector The PSD is the second detector encountered by an incoming particle. It works as an anticoincidence detector (i.e. it is able to discriminate incident γ-rays from charged particles) and provides an additional charge measurement of incoming cosmic-ray nuclei in a range up to Z $\leq$26.[14]

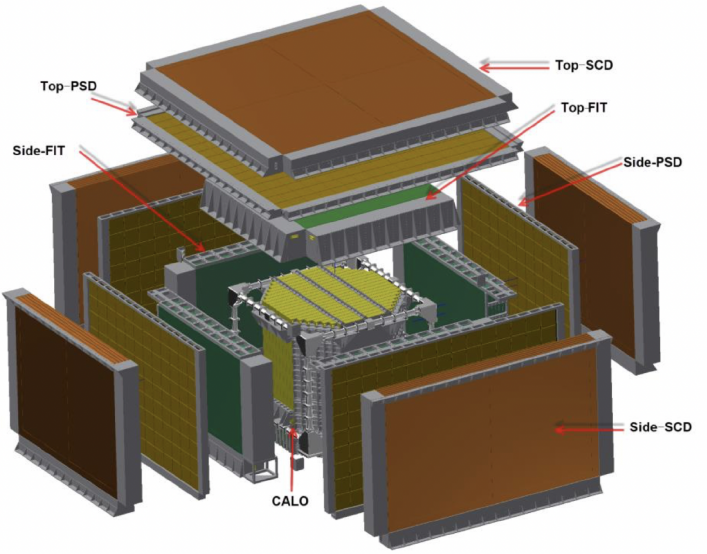

Fig. 4. Exploded model of HERD. In orange the silicon charge detector (SCD), in dark yellow the plastic scintillator detector (PSD), in green the fiber tracker (FIT) and in light yellow the calorimeter (CALO).

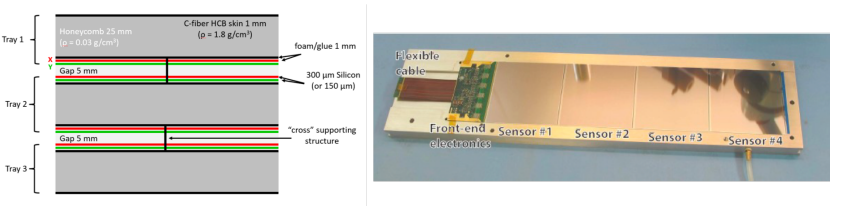

Fig. 5. Scheme of the SCD on the left. A prototype of SCD on the right.

Currently there are two designs for the PSD: one made by plastic scintillator bars the other made by plastic scintillator tiles. In both cases the single detection unit (i.e. bar, tile) is readout by silicon photomultipliers (SiPMs). The use of SiPMs will ensure, in addition to exceptional detection performances, low-weight, negligible power consumption, compactness and non-sensitivity to magnetic fields.

The bar option forsees two orthogonal layers of trapezoidal bars, see FIG. 6

The tile option forsees two staggered layers of square tiles, see FIG. 7.

Both configurations show advantages and disadvantages, mainly related to the optimal number of readout channels versus back–splash (or back–scattering) effects.

Currently both prototypes are undergoing beam tests at CERN with the aim to define the best scintillator type and size as well as SiPM quantity and model.

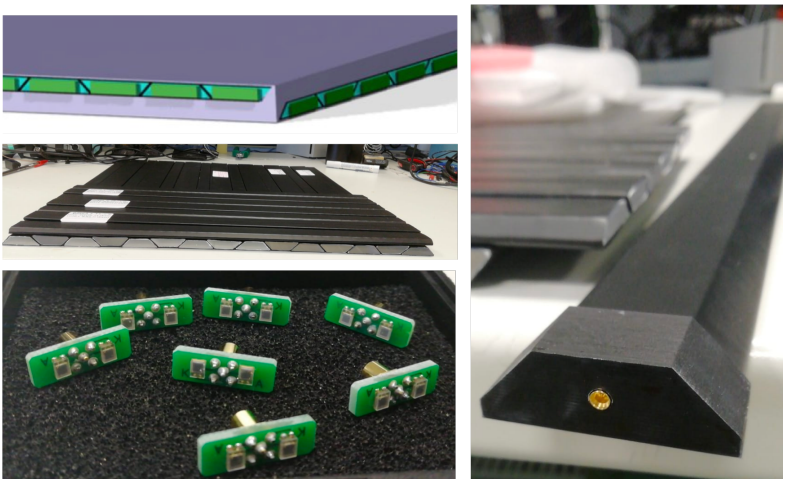

Fig. 6. Scheme of the PSD made with bars on the upper left. The PSD bar prototype undergoing the beam test at CERN on central left. A detail of the SiPMs used for the readout on the bottom left. A detail of the complete detection unit (the bar) undergoing the beam test at CERN on the right.

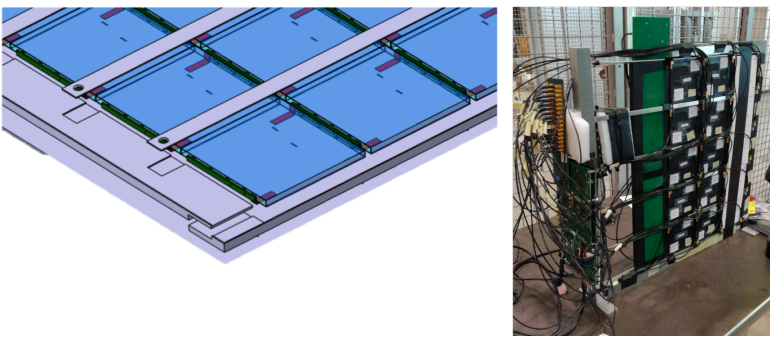

Fig. 7. Detail of the scheme of the PSD made with tiles on the left. The PSD tiles prototype undergoing the beam test at CERN on the right.

Fiber Tracker The FIT is the third detector hit by an impinging particle. It has several aims:

- reconstructing the trajectories and the charge absolute value (Z) of charged cosmic rays;
- favouring the conversion of low energy gamma rays and reconstructing the tracks of the generated electrons and positrons;
- acting as a redundance of the SCD and offering the possibility of cross-calibration among subdetectors.

In the current design,[15] each side of the FIT is made by 7 tracking planes, for 7 independent measurements of the position of a traversing charged particle, see FIG. 8. Each tracking plane consists of two layers measuring the two orthogonal spatial coordinates.

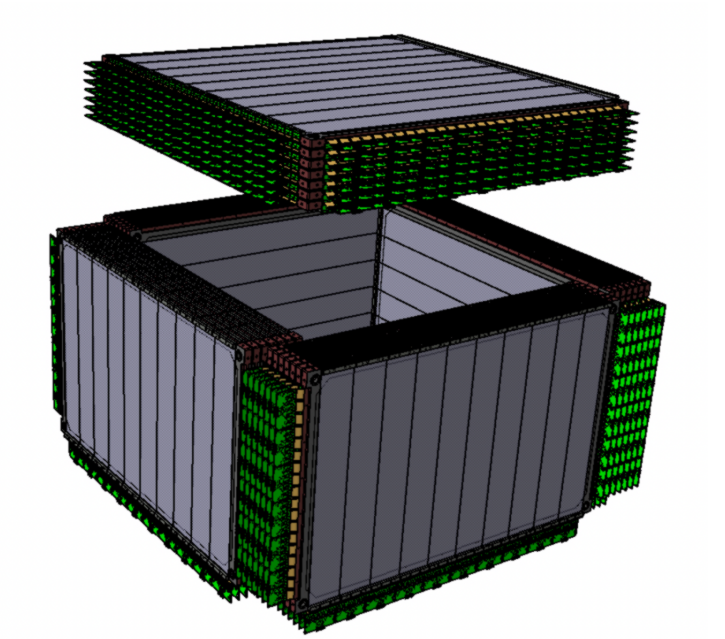

Fig. 8. Scheme of the FIT detector.

The tracking planes of the top sector are made of 10 FIT modules on both the x layers and y layers, while the tracking planes of the side sectors are made of 6 FIT modules on the x layers and 10 FIT modules on the y layers. A module includes one scintillating fiber mat and three SiPM-arrays to readout the scintillation light induced by the particles hitting the mat.

A FIT module prototype made of a 77 cm long fiber mat and one SiPM array was exposed to a 400 GeV/c primary proton beam and a fragmentation ion beam created by a 150 GeV/c lead beam hitting a beryllium target at CERN. A spatial resolution of 45 m and a mean hit efficiency of 99.6% were measured for protons. The response to nuclei from helium up to beryllium was studied and a charge resolution better than 15% was found.

The calorimeter The heart of the HERD instrument is the CALO: it is a homogeneous, isotropic, 3D segmented calorimeter accepting particles coming from each surface.[16] The performance of a detector based on these ideas was accurately studied by the CaloCube *R&D* project. By exploiting those results, the baseline design

of the CALO consists of about 7500 LYSO cubes with edge length of 3 cm, corresponding to about 2.6 radiation lengths (X_0) and 1.4 Moliere radius. The CALO external envelope is similar to an octagonal prism and the crystals are arranged on vertical layers with different dimension, see FIG. 9.

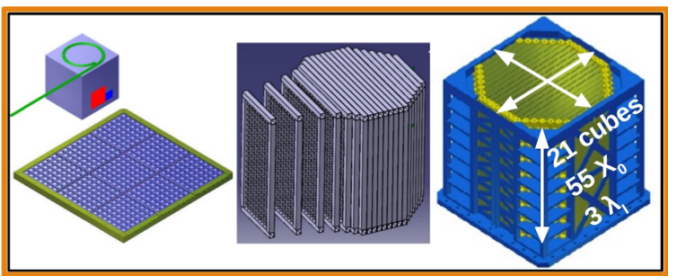

Fig. 9. Scheme of the CALO detector.

The total depth of the CALO for vertical particles is about 55 X_0 (radiation length) and $3\lambda_I$ (interaction length).

The scintillation light of each crystal is read-out by two independent systems: the first one consists of WaveLength Shifting fibers (WLS) coupled to image Intensified scientific CMOS (IsCMOS) cameras, the second one is made of photo-diodes (PD) connected to custom front-end electronics chips named HIDRA. This design, here named "double read-out system", achieves the capability of cross-calibrating the scintillation light measurement. Recent articles by calorimetric CR experiments speculated about the energy scale calibration as a possible source of unknown uncertainty, particularly for the electron flux measurement. Both the "double read-out" system and the TRD detector will strongly increase the understanding of HERD calorimeter energy scale with respect to previous CR detectors. Furthermore, both WLS and PD systems provide independent fast trigger information which will be employed to improve the HERD trigger capabilities.

The Transition Radiation Detector The TRD, installed on a lateral face of the detector, is needed to calibrate the response of the calorimeter to high energy hadronic showers. Ground calibration of space calorimeters, indeed, can only go to 400 GeV at maximum by using CERN SPS beam. For TeV protons, only few particles have showers all contained in the calorimeter and only visible deposited energy is recorded by detectors. Energy of primary proton is then derived by data extrapolation of low energy protons, which is not reliable.

A Transition Radiation Detector (TRD) could be used to calibrate the incident particle with energy in a range in which transition radiation is generated but not saturated. The energy of TR is proportional to the Lorentz factor γ of the incident

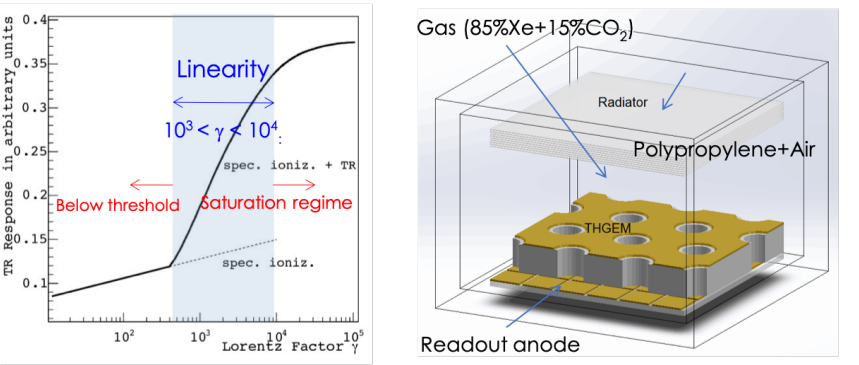

Fig. 10. Working principle of the TRD detector on the left. Scheme of the TRD detector on the right.

charged particle. The radiant photons will be generated at $\gamma{\sim}10^3$ and saturated at $\gamma{\sim}10^4$, the corresponding energy region of proton is about 1-10 TeV, see FIG. 10.

By detecting the X rays generated by TR, the absolute energy of the incident charged particle in the TeV region can be obtained by measuring the Lorentz factor.

The large effective area of TRD is achieved by a modular and highly redundant design. The TRD is arranged in 3 layers each consisting of 9 detection modules. Each detection module consists of a TR radiator, an X-ray gaseous detector with an effective area of $20{\times}20$ cm^2 and read-out electronics, supported by grid-like frames.

4. Summary

The HERD detector will be installed onboard CSS on 2027, with a lifetime of 5–10 years. The main scientific objectives regarding this initiative reside in the fields of CR physics, gamma-rays and (indirect) DM searches.

HERD will be capable of providing high-precision measurements including single-element spectral indexes along with spectral hardenings/softenings of nuclei and it will investigate the "knee" in hadronic CRs, for the first time via direct observations.

Moreover it will provide precise measurements of secondary-to-primary ratios (i.e., B/C) in an extended energy range,giving information on CR propagation in the Galaxy.

A great effort will also be invested in probing fine structures in the leptonic component $(e^+ + e^-)$, especially at the highest-achievable energies with great precision.

HERD will also be involved in high energy gamma-ray observations throughout a broad energy range due to its wide FOV, as well as assisting in observations of ground-based experiments with a narrow FOV.

Acknowledgements

The author would like to thank all members of the HERD Collaboration for supporting this work with valuable comments and fruitful discussions.

THE MARCEL GROSSMANN MEETINGS

Series Editor: REMO RUFFINI

Publications in the Series of Proceedings

Proceedings of the Sixteenth Marcel Grossmann Meeting on General Relativity
(Virtual Meeting, 2021)
Edited by G. Vereshchagin, R. Ruffini
World Scientific, 2022

Proceedings of the Fifteenth Marcel Grossmann Meeting on General Relativity
(Rome, Italy, 2018)
Edited by E.S. Battistelli, R.T. Jantzen, R. Ruffini
World Scientific, 2022

Proceedings of the Fourteenth Marcel Grossmann Meeting on General Relativity
(Rome, Italy, 2015)
Edited by M. Bianchi, R.T. Jantzen, R. Ruffini
World Scientific, 2017

Proceedings of the Thirteenth Marcel Grossmann Meeting on General Relativity
(Stockholm, Sweden, 2012)
Edited by K. Rosquist, R.T. Jantzen, R. Ruffini
World Scientific, 2015

Proceedings of the Twelfth Marcel Grossmann Meeting on General Relativity
(Paris, France, 2009)
Edited by T. Damour, R.T. Jantzen, R. Ruffini
World Scientific, 2012

Proceedings of the Eleventh Marcel Grossmann Meeting on General Relativity
(Berlin, Germany, 2006)
Edited by H. Kleinert, R.T. Jantzen, R. Ruffini
World Scientific, 2007

Proceedings of the Tenth Marcel Grossmann Meeting on General Relativity
(Rio de Janiero, Brazil, 2003)
Edited by M. Novello, S. Perez-Bergliaffa, R. Ruffini
World Scientific, 2005

Proceedings of the Ninth Marcel Grossmann Meeting on General Relativity
(Rome, Italy, 2000)
Edited by V.G. Gurzadyan, R.T. Jantzen, R. Ruffini
World Scientific, 2002

Proceedings of the Eighth Marcel Grossmann Meeting on General Relativity
(Jerusalem, Israel, 1997)
Edited by T. Piran
World Scientific, 1998

Proceedings of the Seventh Marcel Grossmann Meeting on General Relativity
(Stanford, USA, 1994)
Edited by R.T. Jantzen and G.M. Keiser
World Scientific, 1996

Proceedings of the Sixth Marcel Grossmann Meeting on General Relativity
(Kyoto, Japan, 1991)
Edited by H. Sato and T. Nakamura
World Scientific, 1992

Proceedings of the Fifth Marcel Grossmann Meeting on General Relativity
(Perth, Australia, 1988)
Edited by D.G. Blair and M.J. Buckingham
World Scientific, 1989

Proceedings of the Fourth Marcel Grossmann Meeting on General Relativity
(Rome, Italy, 1985)
Edited by R. Ruffini
World Scientific, 1986

Proceedings of the Third Marcel Grossmann Meeting on General Relativity
(Shanghai, People's Republic of China, 1982)
Edited by Hu Ning
Science Press – Beijing and North-Holland Publishing Company, 1983

Proceedings of the Second Marcel Grossmann Meeting on General Relativity
(Trieste, Italy, 1979)
Edited by R. Ruffini
North-Holland Publishing Company, 1982

Proceedings of the First Marcel Grossmann Meeting on General Relativity
(Trieste, Italy, 1975)
Edited by R. Ruffini
North-Holland Publishing Company, 1977

FREEDOM OF MOVEMENT FOR SCIENTISTS

The Marcel Grossmann Meetings were founded with the premise that scientists of all nations have a right to meet to exchange knowledge independent of national borders.

ACKNOWLEDGEMENTS

We acknowledge the outstanding job done before, during and after the meeting by the ICRANet/ICRA administrative and secretarial staff: Cristina Adamo, Silvia Latorre, Elisabetta Natale, and Cinzia di Niccolo. Finally this meeting and its proceedings could not have functioned without the dedicated IT support of the ICRANet system manager Gabriele Brandolini, with some temporary assistance from Domenico La Selva and Damiano Verzulli. We would like to thank Linda Kwan from World Scientific for valuable assistance during preparation of these proceedings.

ORGANIZING BODIES OF THE SIXTEENTH MARCEL GROSSMANN MEETING

INTERNATIONAL ORGANIZING COMMITTEE

Blair David, Choquet Bruhat Yvonne, Damour Thibault, De Bernardis Paolo, Everitt C. W. Francis, Fryer Chris, Haensch Theodor, Henneaux Marc, Jones Christine, Kerr Roy, Kleinert Hagen, Kunz Jutta, Laemmerzahl Claus, Longair Malcolm, Mirabel Felix, Mirzoyan Razmik, Piran Tsvi, Rueda Jorge, Ruffini Remo (chair), Sasaki Misao, Sato Humitaka, Sunyaev Rashid, 't Hooft Gerard, Weinberg Steven, Yau Shing-Tung, Zhang Bing

LOCAL ORGANIZING COMMITTEE

Adamo Cristina, Bianco Carlo Luciano, Brandolini Gabriele A., di Niccolo Cinzia, Latorre Silvia, La Selva Domenico, Li Liang, Loppini Alessandro, Natale Elisabetta, Verzulli Damiano, Vereshchagin Gregory (chair), Wang Yu

INTERNATIONAL COORDINATING COMMITTEE

ALBANIA: Hafizi M. - ARGENTINA: Arguelles C., Scoccola C., Reula O., Romero G.E. - ARMENIA: Sahakyan N. - AUSTRALIA: Blair D., Ju L., Lun A., Manchester D., Melatos A., Quinn P., Scott S.M., Steele J.D. - AUSTRIA: Aichelburg P.C., Schindler S. - BELARUS: Kilin S., Prakapenia M., Siutsou I. - BELGIUM: Henneaux M. - BOLIVIA: Aguirre C.B. - BOSNIA: Pasic V. - BRAZIL: Barres de Almeida U., Coelho Goulart J., Dalmolin F.T., de Lima Rafael C.R., Guzzo M., Maia C., Malheiro M., Romero Filho C.A., Shellard R.C., Zen Vasconcellos C. - BULGARIA: Yazadjiev S. - CANADA: Singh D., Smolin L., Turok N. - CHILE: Bauer F., Bunster W.C., Giacomini A. - CHINA (MAINLAND): Cai R., Cai Y., Cao Z., Chang J., Chen J., Chen X., Dai Z., Feng L.-L., Han W., Jing Y., Li T.-P., Lin W., Lou Y.-Q., Luo J., Mei J., Tam T., Wang A., Wang Y., Wu X.-P., Wu Y.-L., Yuan Y.-F., Zhang B.-B., Zhang S.-N., Zhao G. - CHINA (TAIWAN): Chen Chiang-Mei, Chen Pisin, Lee Da-Shin, Lee Wo-Lung, Ni Wei-Tou - COLOMBIA: Bargueño de Retes P., Gonzalez G., Higuera Garzon M.A., Núñez L., Romano A.E., Valenzuela Toledo C.A., Zuluaga J.I. - CROATIA: Dominis Prester D., Karlica M., Milekovic M., Smolcic V., Smolic I., Suric T. - CUBA: Perez Martinez A., Pérez Rojas H. - CZECH REPUBLIC: Bicak J., Stuchlik Z. - DENMARK: Naselsky P. - ECUADOR: Contreras E. - EGYPT: Tawfik A.N., Wanas M.I. - ESTONIA: Einasto J., Saar E. - FINLAND: Poutanen J., Volovik G. - FRANCE: Brillet A., Buchert T., Chardonnet P., Coullet P., de Freitas Pacheco J.A., Deruelle N., Iliopoulos J., Lamanna G., Mignard F. - GEORGIA: Lavrelashvili George, Machabeli Giorgi - GERMANY: Biermann P., Blumlein J., Di Piazza A., Fritzsch H., Genzel R., Gilmozzi R., Hasinger G., Hehl F., Keitel C., Kiefer C., Mirzoyan R.,

Neugebauer G., Nicolai H., Renn J., Ringwald A., Ruediger A. - GREECE: Batakis N.A., Cotsakis S., Vagenas E.C. - HUNGARY: Fodor G., Levai P. - ICELAND: Bjornsson G., Jakobsson P. - INDIA: Chakrabarti S.K., Iyer B., Padmanabhan T., Souradeep T. - IRAN: Baghram S., Bavarsad E., Eslam Panah B., Firouzjahi H., Haghighat M., Mansouri R., Mashhoon B., Shakeri S., Sobouti Y., Taghi Mirtorabi M. - IRELAND: O'Murchada N. - ISRAEL: Milgrom M., Nakar E., Pe'er A., Piran T. - ITALY: Belinski V., Bianchi M., Bianco C.L., Cherubini C., Della Valle M., Falciano S., Filippi S., Haardt F., Menotti P., Merafina M., Pani P., Ricci F., Treves A., Vereshchagin G.V., Vitale S., Xue S.- S. - JAPAN: Fujimoto M.-K., Makishima K., Nakamura T., Sato K., Shibata M. - KAZAKHSTAN: Abishev M., Aimuratov Y., Boshkayev K., Mychelkin E.G., Spitaleri C. - KOREA (PYEONGYANG): Kim J.S. - KOREA (SEOUL): Kim S.P., Kim S.-W., Lee H.K., Lee H.-W., van Putten M. - KYRGYZSTAN: Gurovich V.Ts. - LIBYA: Gadri M. - MEXICO: Breton N., Cervantes-Cota J.L., Fraija Cabrera N.I., García-Diaz A.A., Macías Alvarez A., Mielke Eckehard W., Quevedo H., Rodriguez L.F. - NETHERLANDS: Slagter R. - NEW ZEALAND: Visser M., Wiltshire D. - NORWAY: Elgaroy O., Fonseca Mota D., Knutsen H. - PAKISTAN: Qadir A., Qamar S. - PERU: Vargas T. - POLAND: Belczynski K., Demianski M., Lewandowski Jerzy, Nurowski P., Sokolowski L. - PORTUGAL: Costa M., Da Silva A., Lemos J.P.S., Lobo F., Moniz P., Silva L.O. - ROMANIA: Visinescu M. - RUSSIA: Aksenov A., Arkhangelskaja I., Bisnovatyi-Kogan G., Blinnikov S., Chechetikin V.M., Cherepaschuk A.M., Khriplovich I., Lipunov V.M., Lukash V.N., Novikov I., Rudenko V.N., Starobinsky A.A. - SERBIA: Djordjevic G., Jovanovic P., Knezevic Z., Pankov-Hzvojevic M., Popovic L., Prodanovic T., Sijacki D., Simic S. - SLOVAKIA: Balek V. - SLOVENIA: Cadez A., Gomboc A., Zavrtanik D. - SOUTH AFRICA: Larena J., Maharaj S. - SPAIN: Elizalde E., Ibanez J., Perez M.J., Verdaguer E. - SWEDEN: Abramowicz M.A., Marklund M., Ryde F. - SWITZERLAND: Durrer R., Jetzer P. - TURKEY: Aliev A., Gurses M. - UKRAINE: Novosyadlyj B., Zaslavskii O., Zhuk A. - UNITED ARAB EMIRATES: Fernini I. - UNITED KINGDOM: Cruise A.M., Frenk Carlos S., Green M., Mavromatos N., Perry M., Willingale R. - USA: Abel T., Ashtekar A., Bardeen J., Carlstrom J., Cornish N., Dermer C., Fan X., Flanagan E., Fraschetti F., Fryer C., Incera V., Jantzen R.T. (chairperson), Kolb R., Laguna P., Lousto C., Madau Piero, Mathews Grant, Matzner Richard, Melia Fulvio, Mester John, Michelson Peter, Nordtvedt Kenneth, Parker Leonard, Pretorius F., Pullin J., Shapiro I., Shapiro S., Shoemaker D., Smoot G., Stiavelli M., Teukolsky S., van Nieuwenhuizen P., Zhang B. - UZBEKISTAN: Ahmedov B., Zalaletdinov R.M. - VATICAN CITY: Gionti G. - VENEZUELA: Fuenmayor E. - VIETNAM: Long H.N.

MARCEL GROSSMANN AWARDS

Sixteenth Marcel Grossmann Meeting

Institutional Awards

"for the creation of the world's best X-ray map of the entire sky, for the discovery of millions of previously unknown accreting supermassive black holes at cosmological redshifts, for the detection of X-rays from tens of thousands of galaxy clusters, filled mainly with dark matter, and for permitting the detailed investigation of the growth of the large-scale structure of the universe during the era of dark energy dominance".

S.A. LAVOCHKIN ASSOCIATION
- presented to its Designer General **Alexander Shirshakov**

MAX PLANCK INSTITUTE FOR EXTRATERRESTRIAL PHYSICS (MPE)
- presented to Professor **Peter Predehl**, Principal Investigator of eROSITA

SPACE RESEARCH INSTITUTE (IKI) OF THE RUSSIAN ACADEMY OF SCIENCES
- presented to Professor **Rashid Sunyaev,** Principal Investigator of SRG Observatory in Russia

Individual Awards

DEMETRIOS CHRISTODOULOU
"For his many lasting contributions to the foundation of mathematical physics including the dynamics of relativistic gravitational fields. Notably for: contributing in 1971, at the age of 19, to derive with Remo Ruffini the mass-energy formula of black holes as a function of their angular momentum, charge and irreducible mass. Christodoulou turned then to the study of partial differential equations and mathematical physics, to which he remained dedicated for the rest of his career. Highlights in this area include the theoretical discovery of the nonlinear memory effect of gravitational waves (Phys. Rev. Letters 1991), the monograph (1993) in collaboration with Sergiu Klainerman on the global nonlinear stability of the Minkowski spacetime, the monograph (2009) on the formation of black holes in pure general relativity by imploding gravitational waves, and the monographs (2007 and 2019) on the formation and further development of shocks in fluids."

GERARD 't HOOFT
"for his persistent devotion to the study of the quantum field theory boundary conditions at the black hole horizon".

TSVI PIRAN
"for extending Relativistic astrophysics across international frontiers, a true companion in the search for the deeper meaning of Einstein's great theory".

STEVEN WEINBERG
"for unwavering support for the MG meetings since their inception, a true companion in the search for the deeper meaning of Einstein's great theory".

Each recipient is presented with a silver casting of the TEST sculpture by the artist A. Pierelli. The original casting was presented to His Holiness Pope John Paul II on the first occasion of the Marcel Grossmann Awards.

15th Marcel Grossmann Meeting
July 2018, Rome, Italy

Institutional Awards

PLANCK SCIENTIFIC COLLABORATION (ESA)
"for obtaining important constraints on the models of inflationary stage of the Universe and level of primordial non-Gaussianity; measuring with unprecedented sensitivity gravitational lensing of Cosmic Microwave Background fluctuations by large-scale structure of the Universe and corresponding B-polarization of CMB, the imprint on the CMB of hot gas in galaxy clusters; getting unique information about the time of reionization of our Universe and distribution and properties of the dust and magnetic fields in our Galaxy"

- presented to Jean-Loup Puget, the Principal Investigator of the High Frequency Instrument (HFI)

HANSEN EXPERIMENTAL PHYSICS LABORATORY AT STANFORD UNIVERSITY
"to HEPL for having developed interdepartmental activities at Stanford University at the frontier of fundamental physics, astrophysics and technology"

- presented to Research Professor Leo Hollberg, HEPL Assistant Director

Individual Awards

LYMAN PAGE
"for his collaboration with David Wilkinson in realizing the NASA Explorer WMAP mission and as founding director of the Atacama Cosmology Telescope"

RASHID ALIEVICH SUNYAEV
"for the development of theoretical tools in the scrutinising, through the CMB, of the first observable electromagnetic appearance of our Universe"

SHING-TUNG YAU
"for the proof of the positivity of total mass in the theory of general relativity and perfecting as well the concept of quasi-local mass, for his proof of the Calabi conjecture, for his continuous inspiring role in the study of black holes physics"

14th Marcel Grossmann Meeting
July 2015, Rome, Italy

Institutional Award

EUROPEAN SPACE AGENCY (ESA)
"for the tremendous success of its scientific space missions in astronomy, astrophysics, cosmology and fundamental physics which have revolutionized our knowledge of the Universe and hugely benefited science and mankind"

- presented to its Director General Johann-Dietrich Woerner

Individual Awards

KEN'ICHI NOMOTO
"for heralding the role of binary systems in the evolution of massive stars"

MARTIN REES
"for fostering Research in black holes, gravitational waves and cosmology"

YAKOV G. SINAI
"for applying the mathematics of chaotic systems to physics and cosmology"

SACHIKO TSURUTA
"for pioneering the physics of hot neutron stars and their cooling"

FRANK C.N. YANG
"for deepening Einstein's geometrical approach to physics in the best tradition of Paul Dirac and Hermann Weyl"

T.D. LEE (award received by Yu-Qing Lou on behalf of Prof. T.D. Lee)
"for his work on white dwarfs motivating Enrico Fermi's return to astrophysics and guiding the basic understanding of neutron star matter and fields"

13th Marcel Grossmann Meeting
July 2012, Stockholm, Sweden

Institutional Award

ALBANOVA
for its innovative status as a joint institute established by Stockholm University and the Royal Institute of Technology and for fostering contributions to cosmology and astrophysics in the profound scientific tradition established by Oskar Klein.

- presented to the Rector of Stockholm University, Prof. Kåre Bremer.

Individual Awards

DAVID ARNETT
for exploring the nuclear physics and yet unsolved problems of the endpoint of thermonuclear evolution of stars, leading to new avenues of research in physics and astrophysics.

VLADIMIR BELINSKI and I.M. KHALATNIKOV
for the discovery of a general solution of the Einstein equations with a cosmological singularity of an oscillatory chaotic character known as the BKL singularity.

FILIPPO FRONTERA
for guiding the Gamma-ray Burst Monitor Project on board the BeppoSAX satellite, which led to the discovery of GRB X-ray afterglows, and to their optical identification.

12th Marcel Grossmann Meeting
July 2009, Paris, France

Institutional Award

INSTITUT DES HAUTES ÉSTUDES SCIENTIFIQUE (IHÉS)
for its outstanding contributions to mathematics and theoretical physics, and notably for having renewed basic geometrical concepts, and having developed new mathematical and physical aspects of spacetime.

- presented to Prof. Jean-Pierre Bourguignon

Individual Awards

JAAN EINASTO
for pioneering contributions in the discovery of dark matter and cosmic web and fostering research in the historical Tartu Observatory.

CHRISTINE JONES
for her fundamental contributions to the X-ray studies of galaxies and clusters tracing their formation and evolution and for her role in collaborations using clusters to study dark matter and in analyzing the effects of outbursts from supermassive black holes on the intracluster gas.

MICHAEL KRAMER
for his fundamental contributions to pulsar astrophysics, and notably for having first confirmed the existence of spin-orbit precession in binary pulsars.

11th Marcel Grossmann Meeting
July 2006, Berlin, Germany

Institutional Award

FREIE UNIVERSITÄT BERLIN
for the successful endeavor of re-establishing — in the spirit of the Humboldt tradition — freedom of thinking and teaching within a democratic society in a rapidly evolving cosmos

- presented to Dr. Dieter Lenzen, President of FUB

Individual Awards

ROY KERR
for his fundamental contribution to Einstein's theory of general relativity: "The gravitational field of a spinning mass as an example of algebraically special metrics."

GEORGE COYNE
for his committed support for the international development of relativistic astrophysics and for his dedication to fostering an enlightened relationship between science and religion.

JOACHIM TRUMPER
for his outstanding scientific contributions to the physics of compact astrophysical objects and for leading the highly successful ROSAT mission which discovered more than 200,000 galactic and extragalactic X-ray sources: a major step in the observational capabilities of X-ray astronomy and in the knowledge of our universe.

10th Marcel Grossmann Meeting
July 2003, Rio de Janeiro, Brazil

Institutional Award

CBPF (Brazilian Center for Research in Physics)
for its role as a teaching and research institution and as a place originating fundamental physics ideas in the exploration of the universe.

- presented to its founders Cesar Lattes, Josè Leite Lopez and Jayme Tiomno

Individual Awards

YVONNE CHOQUET-BRUHAT AND JAMES W. YORK, JR.
for separate as well as joint work in establishing the mathematical framework for proving the existence and uniqueness of solutions to Einstein's gravitational field equations.

YUVAL NE'EMAN
for his contributions to science, epistimology, mathematics and physics from subnuclear to space sciences.

9th Marcel Grossmann Meeting
July 2000, Rome, Italy

Institutional Award

SOLVAY INSTITUTES
for identifying and recording in discussions by the protagonists the crucial developments of physics and astrophysics in the twentieth century.

- presented to Jacques Solvay

Individual Awards

CECILLE AND BRYCE DEWITT
for promoting General Relativity and Mathematics research and inventing the "summer school" concept.

RICCARDO GIACCONI
for opening, five successive times, new highways for exploring the Universe.

ROGER PENROSE
for extending the mathematical and geometrical foundations of General Relativity.

8th Marcel Grossmann Meeting
June 1997, Jerusalem

Institutional Award

HEBREW UNIVERSITY
for its role as a cradle of Science and Humanities and for hosting the manuscripts of Albert Einstein.

- presented to M. Magidor, President of the Hebrew University of Jerusalem

Individual Awards

TULLIO REGGE
for his contributions to the interface between mathematics and physics leading to new fields of research of paramount importance in relativistic astrophysics and particle physics.

FRANCIS EVERITT
for leading the development of extremely precise space experiments utilizing superconducting technology to test General Relativity and the Equivalence Principle.

7th Marcel Grossmann Meeting
June 1994, Stanford, USA

Institutional Award

SPACE TELESCOPE SCIENCE INSTITUTE
for its critical role in the direction and operation of the Hubble Space Telescope, a truly unique international laboratory for the investigation and testing of general relativity in the context of modern astrophysics and cosmology.

- presented to Peter Stockman

Individual Awards

SUBRAHMANYAN CHANDRASEKHAR
for his contributions to the analysis of gravitational phenomena from Newton to Einstein and especially for leading the way to relativistic astrophysics with the concept of critical mass for gravitational collapse.

JIM WILSON
for having built on his experience in nuclear physics, thermonuclear reactions, and extensive numerical simulation to create a new testing ground for the novel concepts of relativistic astrophysics.

6th Marcel Grossmann Meeting
June 1991, Kyoto, Japan

Institutional Award

RITP
for keeping alive first in Hiroshima and them in Kyoto research in relativity, cosmology, and relativistic field theory and the development of a school of international acclaim.

- presented to Professor K. Tomita

Individual Awards

MINORU ODA
for participating in the pioneering work of the early sixties in X-ray astronomy and for his subsequent molding of an agile and diversified Japanese scientific space program investigating the deepest aspects of relativistic astrophysics.

STEPHEN HAWKING
for his contributions to the understanding of spacetime singularities and of the large scale structure of the Universe and of its quantum origins.

5th Marcel Grossmann Meeting
August 1988, Perth, Australia

Institutional Award

THE UNIVERSITY OF WESTERN AUSTRALIA
for its contributions to relativistic astrophysics.

- presented to the Vice Chancellor, Professor Robert Smith

Individual Awards

SATIO HAYAKAWA
for his contributions to research in gamma, X-ray and infrared radiation as well as cosmic rays.

JOHN ARCHIBALD WHEELER
for his contributions to geometrodynamics and Einstein's visions.

4th Marcel Grossmann Meeting
July 1985, Rome, Italy

Institutional Award

THE VATICAN OBSERVATORY
for its contributions to the origin and development of astrophysics.

- presented to His Holiness Pope John Paul II

Individual Awards

WILLIAM FAIRBANK
for his work in gravitation and low temperature physics.

ABDUS SALAM
for his work in unifying fundamental interactions.

Institutional Awards for the Spektrum-Roentgen-Gamma (SRG) mission

"for the creation of the world's best X-ray map of the entire sky, for the discovery of millions of previously unknown accreting supermassive black holes at cosmological redshifts, for the detection of X-rays from tens of thousands of galaxy clusters, filled mainly with dark matter, and for permitting the detailed investigation of the growth of the large-scale structure of the universe during the era of dark energy dominance".

S.A. LAVOCHKIN ASSOCIATION
- presented to its Designer General **Alexander Shirshakov**

MAX PLANCK INSTITUTE FOR EXTRATERRESTRIAL PHYSICS (MPE)
- presented to Professor **Peter Predehl**, Principal Investigator of eROSITA

SPACE RESEARCH INSTITUTE (IKI) OF THE RUSSIAN ACADEMY OF SCIENCES
- presented to Professor **Rashid Sunyaev,** Principal Investigator of SRG Observatory in Russia

S.A. LAVOCHKIN ASSOCIATION
presented to its Designer General **Alexander Shirshakov**

Dr Alexander Shirshakov

S.A. Lavochkin Association created the Navigator space platform carrying German eRosita and Russian ART-XC X-Ray Telescopes, organized the launch of SRG Orbital X-Ray Observatory to the second Lagrangian point of the Sun-Earth system at a distance of 1.5 million km from the Earth and managed the observatory flight and the daily reception of its scientific data on Earth for 23.5 months.

Dr Alexander Shirshakov, Designer General of the S.A. Lavochkin Association, is specialized in design, manufacture, testing, launch and control of S/C for scientific purposes. Among those S/C launched, there are the «Radiostron» Astrophysical Observatory (2011) and the «Spektr-RG» space observatory (2019), while the planned S/C launches are «Luna-25» and «Exomars».

Dr Shirshakov started his career in 1973, working as an engineer of the State Unitary Enterprise «NPO named by S.A. Lavochkin» in Khimki (Russian Federation). Starting from 1989 he has played multiple roles within the Lavochkin Association, been appointed head of the group, head of the sector, head of department, deputy head of the complex, head of the branch, director of the center, deputy head of the Design Bureau, deputy General Designer and deputy General Director.

Dr Shirshakov is an editorial board Member of the reviewed edition of «Vestnik of Lavochkin Association». Since 2017, he is also member of the General Designer council. He has been awarded Honored Mechanical engineer of the Russian Federation as well as Agency-level award of the Russian Federal Space Agency.

MAX PLANCK INSTITUTE FOR EXTRATERRESTRIAL PHYSICS (MPE)
presented to Professor **Peter Predehl**, Principal Investigator of eROSITA

Professor Peter Predehl

eROSITA is the soft X-ray telescope on-board the Russian-German Spektr-RG mission which was successfully launched from Baikonur on July 13, 2019 and placed in a halo orbit around the L2 point. 30 years after ROSAT, eROSITA performs an all-sky survey with an unprecedented sensitivity, spectral and angular resolution. Clusters of galaxies are the largest collapsed objects in the Universe. Their formation and evolution is dominated by gravity, i.e. Dark Matter, while their large scale distribution and number density depends on the geometry of the Universe, i.e. Dark Energy. X-ray observations of clusters of galaxies provide information on the rate of expansion of the Universe, the fraction of mass in visible matter, and the amplitude of primordial fluctuations which are the origin of clusters of galaxies and the whole structure of the universe. eROSITA has been designed to detect at least 100.000 clusters of galaxies and to detect systematically more than 3 million obscured accreting Black Holes. eROSITA will also allow to study the physics of galactic X-ray source

populations, like pre-main sequence stars, supernova remnants and X-ray binaries. The eROSITA telescope consists of seven identical Wolter-1 mirror modules. A novel detector system has been developed by MPE on the basis of the successful XMM-Newton pn-CCD technology. MPE is the scientific lead institute of eROSITA, responsible for the development of the instrument, the operation, the analysis software and data archive. Peter Predehl led this development as Principal Investigator of eROSITA and German lead scientist of the SRG mission for more than 15 years until the completion of the first of eight surveys in 2020. At this time eROSITA has already discovered more than 1 million X-ray sources, more than all X-ray observatories of the last 50 years together. This demonstrates that the design goals of the mission will easily be fulfilled.

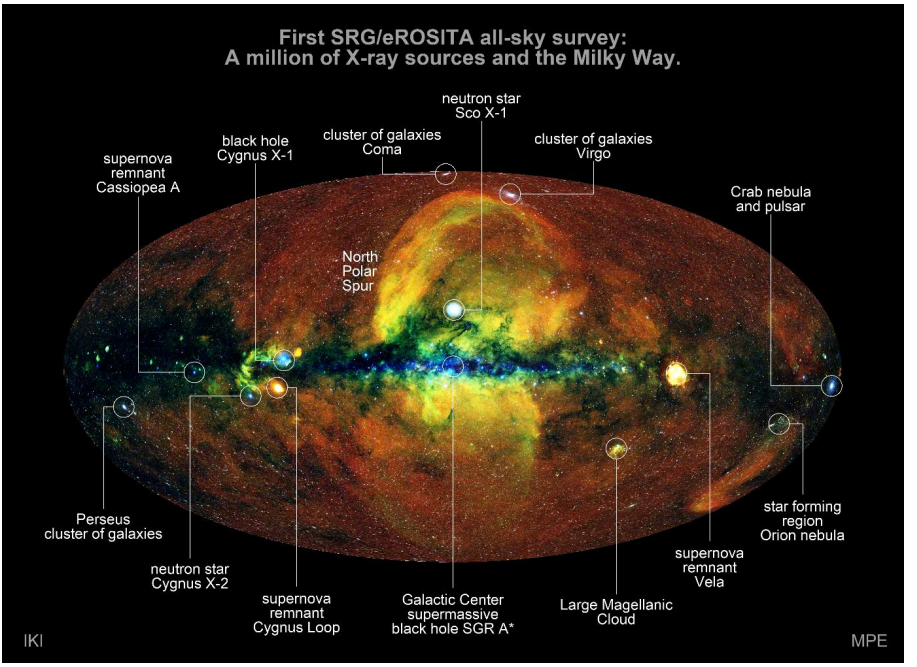
SPACE RESEARCH INSTITUTE (IKI) OF THE RUSSIAN ACADEMY OF SCIENCES
presented to Professor **Rashid Sunyaev**

Professor Rashid Sunyaev

Space Research Institute (IKI) of the Russian Academy of Sciences was responsible for developing the overall concept and scientific program of the SRG Orbital observatory and played a leading role in developing the ART-XC telescope and the entire SRG observatory as part of the Russian space science program carried out by Roskosmos Corporation in the interests of the Russian Academy of Sciences.

During the flight to the L2 point of the Sun-Earth system, SRG with German (eRosita) and Russian (ART-XC named after Mikhail Pavlinsky) X-ray Telescopes aboard performed calibrations and long duration Performance Verification observations of a dozen of targets and deep fields. Starting in the middle of December 2019, the SRG scanned the whole sky three times. During these scans, SRG discovered two million point X-ray sources: mainly quasars, stars with hot and bright coronae, and more than 30 thousand clusters of galaxies. There is a competition and synergy in the search for clusters of galaxies between SRG and the ground-based Atacama Cosmology and South Pole Telescopes, which are searching for clusters of galaxies in microwave spectral band using Sunyaev-Zeldovich effect. SRG provided the X-Ray map of the whole sky in hard and soft bands, the last is now the best among existing. The huge samples of the X-ray selected quasars at the redshifts up to z = 6.2 and clusters of galaxies will be used for well-known cosmological tests and detailed study of the growth of the large scale structure of the Universe during and after reionization. SRG/eRosita is discovering every day several extragalactic objects which increased or decreased their brightness more than 10 times during half of the year after the previous scan of the same one-degree wide strip on the sky. A significant part of these objects has observational properties similar to the Events of Tidal Disruption of a star orbiting in the vicinity of the supermassive black hole. ART-XC discovered a lot of bright galactic and extragalactic transients.

Rashid Sunyaev is the Principal Investigator of SRG mission in Russia, director-emeritus of the Max-Planck Institute for Astrophysics and Maureen and John Hendricks distinguished visiting professor of the Institute for Advanced Study, Princeton.



Individual Awards

Professor **DEMETRIOS CHRISTODOULOU**

"For his many lasting contributions to the foundation of mathematical physics including the dynamics of relativistic gravitational fields. Notably for: contributing in 1971, at the age of 19, to derive with Remo Ruffini the mass-energy formula of black holes as a function of their angular momentum, charge and irreducible mass. Christodoulou turned then to the study of partial differential equations and mathematical physics, to which he remained dedicated for the rest of his career. Highlights in this area include the theoretical discovery of the nonlinear memory effect of gravitational waves (Phys. Rev. Letters 1991), the monograph (1993) in collaboration with Sergiu Klainerman on the global nonlinear stability of the Minkowski spacetime, the monograph (2009) on the formation of black holes in pure general relativity by imploding gravitational waves, and the monographs (2007 and 2019) on the formation and further development of shocks in fluids."

Professor Demetrios Christodoulou

It was back in 1967 that Achille Papapetrou mentioned the case of the 16-year-old Demetrios Christodoulou to John Archibad Wheeler. Wheeler interviewed Demetrios in Paris and brought him immediately to Princeton where he was registered as an undergraduate at the university. After one year he entered the graduate school and started collaborating with me. At the time I was working with Wheeler on the effective potential approach to geodesics co-rotating and counter-rotating (see e.g. reference in The Classical Theory of Fields (Landau and Lifshitz, 1980) in the Kerr metric (later renamed as ISCO; see e.g. (Gravitation Misner, Thorne, Wheeler. 1973). In parallel, Frank Zerilli was working on the gravitational radiation emitted by the fall of a test particle in a Schwarzschild black hole (Zerilli 1970). From these limited conceptual arena Charles Misner and later Kip Thorne launched a program for the detection of gravitational waves on the Earth; see e.g. Misner 1974, Abbott et al. 2016, Abbott et al. 2017. See however Davis et al. 1972, Rodriguez et al. 2018 and J.A. Rueda et al. 2018.

A new approach started with the arrival of Demetrios: he was just creating mathematics following his needs. We identified the reversible and irreversible transformations of a Kerr black hole. Wheeler advanced a thermodynamic analogy. I addressed the need of identifying the concept of irreducible mass (from the Italian "irriducibile"), and was Demetrios's contribution to integrate, overnight, the differential equation for infinitesimal reversible transformations which led to the finite mass-energy formula of a Kerr black hole. That evening, while walking back home through IAS woods, I expressed to Wheeler the great relevance of the newly found formula by Demetrios and proposed to let Demetrios be the single author of this article, admiring his great mathematical talent. Wheeler agreed. The Editor of PRL objected since in that two pages article the Fig. 2 by Wheeler and myself was still unpublished. Actually that Fig. 2 followed a discussion I previously had with Penrose in Florence (Penrose 1961) which allowed us to present there, for the first time, a "Penrose Process". Some difficulties in achieving this process were obvious from the example in Fig. 2, which Roger later recognized himself (Penrose & Floyd 1971). The Editor finally agreed on our written request and the paper appeared on September 17, 1970 (Christodoulou, 1970). On January 1971 appeared my article with Johnny introducing the Black Hole (Ruffini & Wheeler, 1971), with the new physics we were developing in Princeton, including the concept of the "ergosphere". On march 1 1971 we submitted the mass formula of the Kerr Newmann metric, including the relation between the surface area of the horizon and the irreducible (Christodoulou & Ruffini, 1971). On March 11, 1971 the same results were independently confirmed by Steven Hawking, extending further the applicability of our equation (Hawking 1971).

The thesis was successfully discussed by a committee including Eugene Wigner (see Fig. 1), one of the closest collaborators of Albert Einstein and David Wilkinson (see Fig. 2), the head of the NASA WMAP mission, and Johnny and myself as supervisors. The new message was clear: Black Holes, far from being a sink of energy, were energy sources emitting "in principle" 50% of their mass energy, being extractable (Christodoulou & Ruffini, 1971).

Fig. 1 and Fig. 2: Demetrios during his thesis presentation with Eugene Wigner (Fig. 1) and David Wilkinson (Fig.2). Johnny and I were supervisors, ready to intervene in case of need, but no need of intervention was necessary! Wigner elaborated the aphorism of Niels Bohr "Interesting = wrong" in the most definite "very interesting if true = totally wrong".

Demetrios turned soon to the study of partial differential equations and mathematical physics, to which he dedicated for the rest of his career and results were published in four monographs: (Christodoulou and Klainerman 1994, Christodoulou 2007, Christodoulou 2009, Christodoulou 2019). In 1968, Johnny proposed to Demetrios the collapse of a "geon" composed of massless scalar field as a second topic for his thesis. It took almost forty years for him to solve this problem, extended by Demetrios to the focusing of gravitational waves leading to black hole formation (Christodoulou 2009).

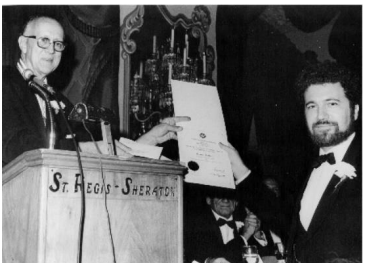


Fig. 3: Prof. Remo Ruffini receiving the Cressy Morrison Award of the New York Academy of Sciences, 1972 for the discovery of the first Black Hole in our galaxy Cygnus X1.

A "long march" started on 12 December 1970 with the launch of the Uhuru satellite by Riccardo Giacconi. Early in 1971 an almost daily conversation with him and Herb Gursky at the Smithsonian Astrophysical Observatory, leading to the discovery of binary X-ray sources. This was soon followedby the announcement of Cygnus X1 identified as the first black hole in our galaxy (Ruffini 1973); see e.g. Gursky & Ruffini 1975, which contained as well the first publicannouncement of the Discovery of Gamma Ray burst, as well as Giacconi & Ruffini 1980, 2009; see Figs. 3 and 4).

Fig. 4: In the second row, from left to right, there are, among others: E. T. Newman, S. Chandrasekhar (Nobel 1983), R. Giacconi (Nobel 2002), R. Ruffini, A. Treves, A. Hewish (Nobel 1974), D. Arnett, J.H. Taylor (Nobel 1993), J. Wilson, R. Penrose (Nobel 2020), as well as J. Bahcall, T. Damour, T. Piran et al.

Today, after fifty years, this "long march" has reached a definite result: through the grandest observational multi-wavelength effort in the history of mankind, from space, ground and underground observatories, we are finally finding evidence that black holes are "alive" and their "extractable energy" in our mass formula (Christodoulou & Ruffini, 1971), is the energy source of the most energetic cosmological sources: gamma ray bursts (GRBs),the active galactic nuclei (AGNs) as well as the ultra-high energy cosmic rays (UHECRs) (Ruffini et al. 2021 and references therein). Their "inner engine", has three independent components: 1) a Kerr black hole which is neither in a stationary state nor in vacuum, 2) a background magnetic field aligned with the black hole rotation axis, and 3) an extremely diluted fully ionized plasma (Moradi et al. 2021).There is no role in this inner engine for ISCO. Indeed a new electro dynamical field equations describe the synchrotron radiation emitted close to the black hole horizon, they point to a discrete and repetitive emission of "blackholic quanta" in the MeV and in the GeV. The magnitudes and the emission time scales of these quanta, for M87 and GRB 130427A, are expressed as a function of the above three parameters (Rueda & Ruffini, 2021). A long lasting GeV emission with a luminosity decreasing as a temporal power law, allows for the first time in GRBs, the determination of the black hole mass and spin as well as their time evolution perfectly fulfilling our mass energy formula (Christodoulou & Ruffini, 1971): a long lasting emission process profoundly different from the traditional process of continued gravitational contraction.

Remo Ruffini

Professor **GERARD 't HOOFT**

"for his persistent devotion to the study of the quantum field theory boundary conditions at the black hole horizon".

Professor Gerard 't Hooft

Prof. Gerard 't Hooft has been a full Professor at the Utrecht University (the Netherlands), since 1977. Nowadays, he is an Emeritus Professor at that University. During his career, he has paid extended scientific visits to CERN (Geneva), Harvard, Stanford, Princeton and Duke University, NC. In 1999, together with M. Veltman, he received the Nobel Prize in Physics, awarded by The Royal Swedish Academy of Sciences, *"For elucidating the quantum structure of electroweak interactions in physics"*.

Prof. 't Hooft's main subjects of research includes:

– Gauge Theories for the sub-atomic particles and forces, various aspects and ingredients of what is now called "The Standard Model of the sub-atomic particles: renormalizability, topological features such as magnetic monopoles and instantons, 1/N expansions.

– Theories for the quantization of the gravitational force and black holes: producing models for the quantum properties of a black hole, as derived from Standard Model and General Relativity alone; its topological features such as antipodal identification.

– Fundamental theories underlying quantum mechanics, in particular returning determinism and reality to the dynamics of the tiniest material entities in his universe.

Prof. 't Hooft has been awarded the Wolf Prize of the State of Israel (1982), the Pius XI Medal (Vatican City, 1983), the Lorentz Medal (KNAW Amsterdam, 1986) as well as the Spinoza Premium (Netherlands Organization for Scientific Research NWO, 1995).

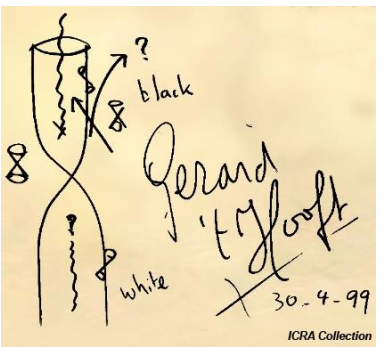

Fig. 2: The signature of Gerard 't Hooft on the wall of ICRA Room 301 (April 4, 1999).

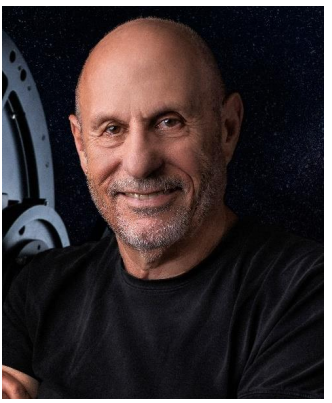
A special event took place at ICRA on April 30, 1999. Prof. Ruffini invited Gerard 't Hooft to Rome to discuss a boundary condition for a quantum field on the black hole horizon, a topic Prof. Ruffini discussed in a previous article "Black-hole evaporation in the Klein-Sauter-Heisenberg-Euler formalism" with Thibault Damour (Phys. Rev. D 14, 332, 1976), but which needed to be examined in more detail. Prof. Ruffini planned to direct Gerard's attention to some specific aspects of this problem. Because we have traditionally been very attentive in spending ICRA travel funds, ICRA offered Gerard to come to Rome on a reduced fare weekend ticket arriving Friday and departing Monday. He had a great relaxing weekend together with Prof. Ruffini following his seminar, which among other things allowed Gerard to sign the wall in our ICRA Room (see Fig. 2), and during this splendid Rome spring weekend he also was able to find a missing factor of 2 in a formula in Prof. Ruffini's 1971 paper with Demetri Christodoulou on the black hole mass formula. The following October, Gerard received the Nobel prize, which meant that we could no longer get away with bringing him to Rome on a cheap ticket! Ever since Gerard has been in our MG IOC helping us with the preparation of the meetings. We are very happy to announce this MG16 Award to Gerard 't Hooft with the motivating phrase *"for his persistent devotion to the study of the quantum field theory boundary conditions at the black hole horizon"*.

Remo Ruffini

Professor **TSVI PIRAN**

"for extending relativistic astrophysics across international frontiers, a true companion in the search for the deeper meaning of Einstein's great theory".



Professor Tsvi Piran

Tsvi Piran is the emeritus Schwartzmann professor at the Hebrew University of Jerusalem. He obtained his PhD in Physics, in 1976 from the Hebrew University working on the collisional Penrose process. Piran returned to the Hebrew University at 1981after being a post doc at Oxford and Texas and a long-term member at the IAS at Princeton. In 1982 he initiated and directed the first ever summer school on Gravitational Waves that took place at Les Houches. Piran was a visiting professor at Harvard, Columbia and New York and a Moore scholar at Caltech.

Piran's research deals with numerous aspects of relativistic astrophysics, ranging from the foundation of numerical relativity to modeling of observer relativistic phenomena and analytic work on the fate of gravitational collapse. Piran's research work focuses mostly on black holes and in particular on gamma-ray bursts. He was among the first to point out their cosmological origin and their association with merging neutron stars and heavy r-process nucleo synthesis. Piran's achievements were recognized in the 2019 EMET prize for Physics.

Professor **STEVEN WEINBERG**

"for unwavering support for the MG meetings since their inception, a true companion in the search for the deeper meaning of Einstein's great theory".

Professor Steven Weinberg. Photo courtesy of Matt Valentine.

Steven Weinberg is a member of the Physics and Astronomy Departments at The University of Texas at Austin. His research has covered a broad range of topics in quantum field theory, elementary particle physics and cosmology. He has been honored with numerous awards, including the Nobel Prize in Physics, the National Medal of Science, the Heinemann Prize in Mathematical Physics and in 2020, the Breakthrough Prize. He is a member of the US National Academy of Sciences, Britain's Royal Society, and other academies in the USA and abroad. The American Philosophical Society awarded him the Benjamin Franklin Medal, with a citation that said he is "considered by many to be the preeminent theoretical physicist alive in the world today." His books for physicists include *Gravitation and Cosmology*, the three-volume work *The Quantum Theory of Fields*, *Cosmology* and published in April of 2021, *Foundations of Modern Physics*. Educated at Cornell, Copenhagen, and Princeton, he also holds honorary degrees from sixteen other universities. He taught at Columbia, Berkeley, M.I.T., and Harvard, where he was Higgins Professor of Physics, before coming to Texas in 1982.

Fig. 1: Chuo Pei Yuan and Cheng Ning Yang at MG2 in Trieste, Italy (1979).

The Sixteenth Marcel Grossmann Meeting (MG16) is a very special one in many respects: it will take place during a pandemic and in spite of the many difficulties, we have decided not to postpone it but to organize it as a virtual meeting. As described on the MG series webpage, these meetings started in 1975 with the first meeting at the International Centre for Theoretical Physics (ICTP) in Trieste (Italy) that I organized with Nobel Prize winner Abdus Salam. A second meeting followed in 1979, with a significantly larger participation including Nobel Laurate Cheng Ning Yang and a Chinese delegation led by Chuo Pei Yuan (see Fig. 1), including Fang Li-Zhi who had accompanied me during my entire first visit to China in 1979. The first truly international MG meeting followed in 1982 in Shanghai (China):this represented an especially important step forward both for the meeting and for China. A multi-millennia *"motto"* in China, which was then proclaimed on banners everywhere, read *"Friends from all over the world are welcomed"*.

We were soon at an impasse over the participation of scientists from Israel, since no diplomatic relations existed between China and Israel at that time and the Israeli scientists were not to be allowed to attend the meeting. A long negotiation began. The boundary conditions were clearly set by Steven Weinberg, a member of the present MG16 IOC: no MG meetings on Einstein's theory of general relativity could occur without the participation of Israeli scientists. The intervention of Yuval Ne'emann, also a member of the MG IOC then as well as the Minister of Science of Israel (see Fig.2), proposed a compromise that would admit at least one Israeli scientist. I went to Beijing alone, meeting every morning for a week with 12 Chinese representatives led by Chuo Pei Yuan going over all possible options. I stayed in an isolated villa not far from Tiananmen Square, accompanied by the 3 volumes of Matteo Ricci (RI MA TO) to keep me company. No solution was in sight the entire week. At the last moment, just before my departure, an agreement was finally reached allowing two Israeli scientists into China. The historic compromise would admit Gerard Tauber and Tsvi Piran into China using a special ICRA travel document I had proposed for them to be able to participate in the meeting, accepted by the Chinese Ambassador in Rome. This modified the thousand-year Chinese *"motto"* to read *"Scientists from all over the world are welcomed"*. The event was extremely beneficial for China and signaled the truly international nature of the MG meetings.

Fig. 2: From right to left: Chaim Weizmann, President of Israel; Yuval Ne'emann, Minister of Science of Israel; R. Ruffini.

I kept on meeting Tauber in the years which followed (see Fig. 3). Soon after, Yuval Ne'emann visited China. The development of bilateral relations, including military cooperation and economical tights, grow exponentially until the establishment of normal diplomatic relations between Israel and China in 1992.

Fig. 3: From right to left: Arrigo Finzi, Remo Ruffini, Gerard Tauber and Konrad Bleuler.

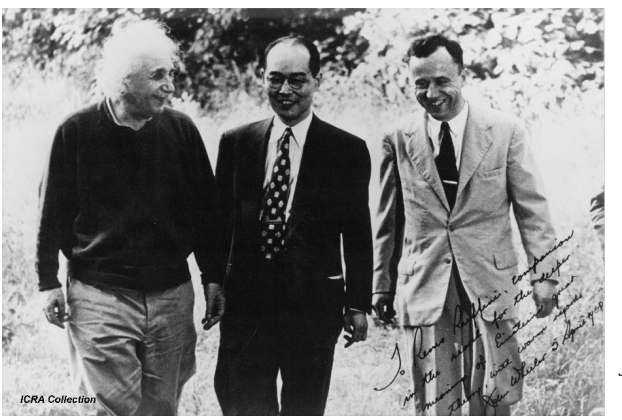


Fig. 4: Albert Einstein, Hideki Yukawa and John. A. Wheeler with a hand-written dedication to Remo Ruffini "To Remo Ruffini, companion in the search for the deeper meaning of Einstein great theory. With warm regards, John Wheeler 5 April 1968".

Given their key role played in the foundations of the MG meetings, I am very happy to propose on behalf of the MG16 IOC, two special Marcel Grossmann Individual Awards: one to Steven Weinberg for *"for unwavering support for the MG meetings since their inception, a true companion in the search for the deeper meaning of Einstein's great theory"* and another one to Tsvi Piran, *"for extending Relativistic astrophysics across international frontiers, a true companion in the search for the deeper meaning of Einstein's great theory"*, in the words of John A. Wheeler's photo dedication to me (see Fig. 4).

Remo Ruffini

PREFACE

Since 1975, the Marcel Grossmann Meetings on Recent Developments in Theoretical and Experimental General Relativity, Gravitation, and Relativistic Field Theories have been organized in order to provide opportunities for discussing recent advances in gravitation, general relativity and relativistic field theories, emphasizing mathematical foundations, physical predictions and experimental tests. The objective of these meetings is to elicit exchange among scientists that may deepen our understanding of spacetime structures as well as to review the status of ongoing experiments aimed at testing Einstein's theory of gravitation either from the ground or from space. Previous meetings have been held in Trieste (MG1: 1975) and (MG2: 1979), Shanghai (MG3: 1982), Rome (MG4: 1985, MG9: 2000), Perth (MG5: 1988), Kyoto (MG6: 1991), Stanford (MG7: 1994), Jerusalem (MG8: 1997), Rio (MG10: 2003), Berlin (MG11: 2006), Paris (MG12: 2009), Stockholm (MG13: 2012), MG14 in 2015 and MG15 in 2018 both in Rome.

Due to the COVID-19 pandemic spreading in the last two years the decision was taken to organize the Sixteenth Marcel Grossmann meeting for the first time in history entirely online. Despite numerous challenges, related to the organization of large worldwide event, MG16 showed the strongest ever interest from the scientific community with a record-breaking number of almost 1200 registered participants and of more than 1000 speakers.

The traditional six-day schedule has been modified to account for different time zones of the speakers and each day the program of the meeting was divided in three blocks with the reference to the Central European Summer Time. The first block was starting at 06:30 in the morning, allowing comfortable time for speakers from Asia and Oceania. The second block was held in the daytime in Europe and Africa. The third block was starting in the afternoon and ending at 19:30 allowing accommodation of the speakers from the Americas. Each day the blocks of plenary sessions were interchanging with the blocks of about 30 parallel sessions each, making this one of the most intense MG meetings ever. All this was possible thanks to recent developments in communication technologies. The Indico open-source software was selected as a web platform for this meeting, while Zoom platform was adopted for the video-conferencing. The meeting was streamed on ICRANet YouTube channel.

The meeting started on Monday July 5 with the Award ceremony. The individual awards went to Demetrios Christodoulou, Tsvi Piran, Gerard 't Hooft and Steven Weinberg, while the Institutional Awards went to the S.A. Lavochkin Association, to the Max Planck Institute for Extraterrestrial Physics – MPE and to the Space Research Institute IKI of the Russian Academy of Sciences. Overall there were 54 plenary talks, 4 public lectures and 5 roundtables and about 90 parallel sessions. The plenary session "Events in Relativistics Astrophysics" on Monday have seen the contributions from Rashid Sunyaev, Michael Kramer, James Miller-Jones, Felix Mirabel. The public lectures were delivered by Razmik Mirzoyan, Asghar Qadir

and Mohammad Bagheri. Plenary talks on Tuesday session "Black holes and the Quantum" by Juan Maldacena, Ahmed Almheiri, Gerard 't Hooft, Mihalis Dafermos, Sergiu Klainerman, Abhay Ashtekar and Frank Wilczek were bracketed by two roundtables on "New results from SRG/eRosita" with the participation of Andrea Merloni, Prof. Rashid Sunyaev, Alexander Lutovinov, Chandreyee Maitra, Esra Bulbul and "Solar neutrinos and Borexino" with the participation of Gianpaolo Bellini and Wick Haxton. Plenary talks on Wednesday in the session "Lambda CDM tensions" by George Efstathiou, Scolnic Daniel, Marc Kamionkowski, Wendy Freedman, Priya Natarajan and Licia Verde were followed by the roundtable "Precision cosmology" with the participation of Licia Verde, Marc Kamionkowski, Piero Rosati, and the public lecture by Francis Halzen. Two blocks of Thursday plenary sessions "Black holes in GRBs" and "Precision tests" included the talks by Roy Kerr, Yuan Ha, Lorenzo Amati, Elena Pian, Carlos Raúl Argüelles, Di Li, Jianglai Liu, Claus Lämmerzahl, Gerhard Heinzel and Ignazio Ciufolini and were followed by the roundtable "GRB 170817A and GRB 190829A" with the participation of Eleonora Troja, Liang Li, Rahim Moradi, Jorge Armando Rueda Hernandez. Two plenary blocks on Friday "Massive stars" and "Physics behind stellar collapse" included the talks by Selma de Mink, Norbert Langer, Jiri Bicak and Tomáš Ledvinka, Ivan De Mitri, Rahim Moradi and Giancarlo Cella. Finally, two plenary blocks on Saturday "Current and future missions" have seen the talks by Shuang-Nan Zhang, Weimin Yuan, Makoto Tashiro, Ruoyu Liu, Jean-Luc Atteia, Jim Hinton and Nicholas White and were followed by the roundtable "What is in our Galactic center" with the participation of Reinhard Genzel, Carlos Raúl Argüelles, Andreas Krut, Jorge Armando Rueda Hernandez, Eduar Becerra Vergara. The program of the meeting can be found at the official website http://www.icra.it/mg/mg16 and at ICRANet Indico website https://indico.icranet.org/event/1/.

These proceedings include about 400 papers containing the results presented at the Sixteenth Marcel Grossmann meeting. The plenary papers from the meeting have been published in International Journal of Modern Physics D as they were submitted. The table of contents includes also the links to YouTube videos with talks given at the meeting and cover plenary talks, public lectures, roundtables and all parallel sessions. The general link to the videos from MG16 is: https://www.youtube.com/watch?v=QFe1lsSid-o&list=PLr5RLbSWSonsaOnZukBDs0qsNIWM8AvRF.

As the editors we would like to express our gratitude to all the chairpersons of the parallel sessions at MG16, who peer-reviewed the papers submitted for these proceedings, as well as to the ICRANet secretariat office and in particular to Cinzia di Niccolo, Elisabetta Natale and Yasmina Di Domizio, as well as to ICRANet system manager Gabriele Brandolini for their help in preparation of this publication.

Preface xxxvi

PART A
PLENARY SESSIONS

New results from testing relativistic gravity with radio pulsars
Michael Kramer 3

Dragging of inertial frames by matter and waves
Jiří Bičák and Tomáš Ledvinka 22

Probes of the progenitors, engines and physics behind stellar collapse
Chris L. Fryer 39

The observation of high-energy neutrinos from the cosmos: Lessons learned for multimessenger astronomy
Francis Halzen 59

The first results of PandaX-4T
Jianglai Liu on behalf of the PandaX Collaboration 85

XRISM: X-ray imaging and spectroscopy mission
Makoto S. Tashiro and the XRISM team 95

The SVOM mission
J.-L. Atteia, B. Cordier and J. Wei on behalf of the SVOM Collaboration 104

Quantum field theory with boundary conditions at the horizons
Gerard 't Hooft 133

The development of general relativity and the cosmological constant
Asghar Qadir 143

The irreducible mass of Christodoulou-Ruffini-Hawking mass formula
Yuan K. Ha 154

Reshaping our understanding on structure formation with the quantum nature of the dark matter
C. R. Argüelles, E. A. Becerra-Vergara, A. Krut et al. 164

First results of LHAASO
Ruo-Yu Liu for the LHAASO Collaboration 180

On the MG16 awards 2021
Remo Ruffini 196

The white dwarf binary merger model of GRB 170817A
J. A. Rueda, R. Ruffini, Liang Li et al. 217

PARALLEL SESSIONS

Accretion

• MHD Processes Near Compact Objects
Chairperson: Sergey Moiseenko
YouTube link: https://youtu.be/2WMTg06ZmV8

A semi-implicit multidimensional unstructured gas dynamical solver for astrophysical applications
Ilya A. Kondratyev and Sergey G. Moiseenko 242

Magnetized neutron stars propagating through a non-uniform ISM
O. D. Toropina, M. M. Romanova and R. V. E. Lovelace 255

Calculation of the kinetic coefficients of arbitrary degenerate electrons in magnetized dense matter
M. V. Glushikhina and G. S. Bisnovatyi-Kogan 264

Modeling of magnetic fields of accretion discs, using no-z- and RZ-approximations
M. V. Pashentseva and E. A. Mikhailov 272

• Accretion Discs and Jets
Chairpersons: Audrey Trova and Shokoufe Faraji
YouTube link: https://youtu.be/29Wj9RCVEKw

Limiting effects in tori clusters
D. Pugliese and Z. Stuchlik 280

Hydrodynamical transport of angular momentum in accretion disks in the presence of nonlinear perturbations due to noise
Subham Ghosh and Banibrata Mukhopadhyay 295

Properties of accretion disc models in the background quadrupole
Shokoufe Faraji 307

Magnetized tori around a uniformly accelerating black hole
Shokoufe Faraji and Audrey Trova 317

Multifrequency behaviour of high mass X-ray binaries (Time lag between optical and X-ray outbursts)
Franco Giovannelli 321

Active Galactic Nuclei

• The Black Hole in M87
Chairpersons: Brian Punsly and Jorge Rueda
YouTube link: https://youtu.be/l1lTgksyJag

Rotation of the crescent image of M87* and polarization of its ESE hotspot
Krzysztof Nalewajko 339

Magnetic reconnection in jet-accretion disk systems
Chandra B. Singh, Elisabete M. de Gouveia Dal Pino, Luis H. S. Kadowaki et al. 344

• Machine Learning in Astronomy: AGN, Transient Events, Cosmology and Others
Chairpersons: Rahim Moradi and Yu Wang
YouTube link: https://youtu.be/ErqrmMZQsBk

Exact fractal model of the universe and possible machine learning methods for the verification of the fractality
A. A. Kirillov, E. P. Savelova and P. O. Vladykina 352

Estimating the photometric redshifts of galaxies and QSOs using regression techniques in machine learning
A. Momtaz, M. H. Salimi and S. Shakeri 368

Deep learning in quasar physics
F. Rastegar Nia, M. T. Mirtorabi, R. Moradi, Y. Wang and A. Vafaei Sadr 382

Cosmological density field emulation and gravitational wave inference based on dimensionality reduction and supervised machine learning
Miguel Conceição, António da Silva and Alberto Krone-Martins 391

Unsupervised photometric detection of galaxy cluster candidates in large surveys
Ana Carvalho, Alberto Krone-Martins and Antonio da Silva 409

• Multiwavelength and Multi-Messenger Observations of Active Galactic Nuclei
Chairpersons: Paolo Giommi and Narek Sahakyan

• **Mathematical Problems of Relativistic Physics: Classical and Quantum**
Chairpersons: A. Shadi Tahvildar-Zadeh and Michael Kiessling

YouTube links: https://youtu.be/9Dr3M9Kb2jo
https://youtu.be/gMOykpapJ5A

The hypercomplex medium as storage of physical equations
Alexander P. Yefremov 605

The Maxwell-Bopp-Landé-Thomas-Podolsky-Einstein system for a static point source
Érik Amorim 619

On recent developments in the theory of relativistic dissipative fluids
V. Hoang 627

Adiabatic solutions in general relativity as null geodesics on the space of boundary diffeomorphisms
Emine Şeyma Kutluk 635

The point spectrum of the Dirac Hamiltonian on the zero-gravity Kerr-Newman spacetime
M. Kiessling, E. Ling and A. S. Tahvildar-Zadeh 648

Causal fermion systems: Classical gravity and beyond
Felix Finster 661

Newman-Penrose-Debye formalism for fields of various spins in pp-wave backgrounds
Aleksandr Kulitskii and Elena Yu Melkumova 679

Gravitational geometric phase
Banibrata Mukhopadhyay, Tanuman Ghosh and Soumya Kanti Ganguly 689

Retarded potentials and radiation in odd dimensions
D. V. Gal'tsov and M. Khlopunov 699

Wave propagation in the anti-deSitter optical metric
D. García-Peláez and C. S. López-Monsalvo 713

New approaches to constrained dynamics and Hamilton-Jacobi procedures in general relativity
D. Salisbury, J. Renn and K. Sundermeyer 719

Orientability of space from electromagnetic quantum fluctuations
N. A. Lemos and M. J. Rebouças 725

Essential self-adjointness of Dirac operators under the influence of general-relativistic gravity
Michael K.-H. Kiessling, A. Shadi Tahvildar-Zadeh and Ebru Toprak 736

• **Wormholes, Energy Conditions and Time Machines**
Chairpersons: Francisco Lobo and Diego Rubiera-Garcia

YouTube links: https://youtu.be/tu_3Wqcd9Ys
https://youtu.be/NqN1c-2fv8Y

Relic magnetic wormholes as possible source of toroidal magnetic fields in galaxies
A. A. Kirillov and E. P. Savelova 743

Wormhole geometries induced by action-dependent Lagrangian theories
Ismael Ayuso, Francisco S. N. Lobo and José P. Mimoso 756

Gravitational lensing by wormholes in binary systems
S. Pietroni 774

Hyper-fast positive energy warp drives
E. W. Lentz 779

From black-bounce to traversable wormhole, and beyond
Alex Simpson 787

Tractor beams, pressor beams, and stressor beams within the context of general relativity
Matt Visser, Jessica Santiago and Sebastian Schuster 808

A singularity theorem for evaporating black holes
E.-A. Kontou, B. Freivogel and D. Krommydas 822

Circularly symmetric thin-shell wormholes in F(R) gravity with (2+1)-dimensions
Cecilia Bejarano, Ernesto F. Eiroa and Griselda Figueroa-Aguirre 831

Warp drive dynamic solutions considering different fluid sources
Osvaldo L. Santos-Pereira, Everton M. C. Abreu and Marcelo B. Ribeiro 840

Symmetries and geometry of spacetime: Towards a new paradigm
Francisco Cabral, Francisco S. N. Lobo and Diego Rubiera-Garcia 856

• Theories of gravity: Alternatives to the cosmological and particle standard models
Chairpersons: Stefano Bellucci and Orlando Luongo

YouTube links: https://youtu.be/-aQcrYoQfBM
https://youtu.be/WsCwPb5OQhY
https://youtu.be/JMnrUfBgqVU
https://youtu.be/pPhZY-bbsew

Thermodynamics of scalar-tensor gravity: A new approach
Valerio Faraoni 876

Two body dynamics in a quadratic modification of general relativity
Soham Bhattacharyya 883

Alternatives to Λ: Torsion, generalized couplings, and scale invariance
C. J. A. P. Martins, C. M. J. Marques, C. B. D. Fernandes et al. 907

Model-independent test of scalar-tensor gravity theory by reconstructing scalar mode of GW170817
Yuya Gushima and Kazuhiro Hayama 921

Cosmology in the novel scalar-tensor representation of $f(R,T)$ gravity
Tiago B. Gonçalves, João Luís Rosa and Francisco S. N. Lobo 932

On the interaction between electromagnetic, gravitational, and plasma related perturbations on LRS class II spacetimes
P. Semrén 943

Condition for expansion-collapse duality between Einstein and Jordan frames
Dipayan Mukherjee, H. K. Jassal and Kinjalk Lochan 958

The model of dark energy based on the quantum-mechanical uncertainty relation
Yu. V. Dumin 967

• Conformal Dilaton Gravity and Related Issues
Chairperson: Reinoud Jan Slagter

YouTube link: https://youtu.be/A3Ygi3YBs5A

Conformal dilaton gravity, antipodal mapping and black hole physics on a warped spacetime
R. J. Slagter 978

From neutrino masses to the full size of the universe — Some intriguing aspects of the tetron model
B. Lampe 999

Summary parallel session AT5
Reinoud Jan Slagter 1014

• Horava-Lifshitz Gravity
Chairperson: Anzhong Wang

YouTube links: https://youtu.be/vPT1dH1zITE
https://youtu.be/5z7zhpiDOpw

Boundary conditions for the Klein-Gordon field on Lifshitz spacetimes
Lissa de Souza Campos 1017

Dynamical system analysis of Bianchi-I spacetimes in $f(R)$ gravity
Saikat Chakraborty, Kazuharu Bamba and Alberto Saa 1026

Cosmological implications in modified Hořava-Lifshitz gravity
Abdul Jawad, Kazuharu Bamba and Farwa Khurshid 1038

Finite action principle and wormholes
Jan Chojnacki and Jan Kwapisz 1046

Strange quark stars in Hořava gravity
Grigoris Panotopoulos 1054

Shadows of Kerr-like black holes in $4D$ Einstein–Gauss–Bonnet gravity and constraints from EHT observations
Sushant G. Ghosh and Rahul Kumar Walia 1069

Wormhole interaction in 2d Horăva-Lifshitz quantum gravity
Jan Ambjørn, Yuki Hiraga, Yoshiyasu Ito and Yuki Sato 1084

Nature of singularities in vector-tensor theories of gravity
V. H. Satheeshkumar 1095

Hořava-Lifshitz and Einstein-Æther gravity in the light of Event Horizon Telescope observations of M87*
Emmanuel N. Saridakis 1104

Hořava-Lifshitz gravity in $(3 + 1)$ dimensions coupled with anisotropic matter and possible constraints from GRB 170817A
Tao Zhang and Fu-Wen Shu 1112

Summary of the parallel session AT6
Anzhong Wang 1119

• Ghost-Free Models of Modified Gravity: Massive Gravity, Horndeski and DHOST Theories, Other Related Models; Their Properties and Solutions
Chairpersons: Dmitry Gal'tsov and Michael Volkov

YouTube links: https://youtu.be/l8KHUPnT2D8
https://youtu.be/48OHIKpgNqs

Non-local R^2-like inflation, gravitational waves and Non-Gaussianities
K. Sravan Kumar 1124

Palatini kinetic scalar-tensor theory: Analytical and numerical solutions
D. V. Gal'tsov and D. S. Bushuev 1136

PART B

Black Holes: Theory and Observations/Experiments

• Theoretical and Observational Studies of Astrophysical Black Holes
Chairperson: Alexander Zakharov

YouTube links: https://youtu.be/fiv_MH-N2kw
https://youtu.be/GYoOb17GvE8

Reconstruction of a star motion in the vicinity of black hole from the redshift of the electromagnetic spectrum
S. O. Komarov and A. K. Gorbatsievich 1151

Shadows of hairy Kerr black holes and constraints from M87*
Sushant G. Ghosh and Misba Afrin 1167

Displacement memory and BMS symmetries
Shailesh Kumar 1179

Physical black holes in semiclassical gravity
Sebastian Murk and Daniel R. Terno 1196

• Black Hole Thermodynamics
Chairperson: Hernando Quevedo

YouTube links: https://youtu.be/XmZDf5mrXQk
https://youtu.be/amseL2qykfk

Information recovery from evaporating rotating charged black holes
Zhi-Wei Wang, Samuel L. Braunstein and Saurya Das 1212

Black hole thermodynamics from entanglement mechanics
S. Mahesh Chandran and S. Shankaranarayanan 1223

Thermodynamics of charged black hole
M. Sharif and Amjad Khan 1238

Rindler trajectories and Rindler horizons in the Schwarzschild spacetime
Kajol Paithankar and Sanved Kolekar 1250

Linear growth of the two-point function for the Unruh state in $1+1$ dimensional black holes
Paul R. Anderson, Zachary P. Scofield and Jennie Traschen 1255

Stress-energy tensor for a quantized scalar field in a four-dimensional black hole that forms from the collapse of a null shell
Shohreh Gholizadeh Siahmazg, Paul R. Anderson, Raymond D. Clark and Alessandro Fabbri 1265

Microscopic model building for black hole membranes from constraints of symmetry
Swastik Bhattacharya and S. Shankaranarayanan 1275

Einstein-Maxwell-Dilaton-Axion mass formulas for black holes with struts and strings
Dmitri Gal'tsov, Gérard Clément and Igor Bogush 1291

• Black Holes in Alternative Theories of Gravity
Chairpersons: Jutta Kunz and Kamal Hajian

YouTube links: https://youtu.be/FRNGJKhiw7c
https://youtu.be/Tjfmuut1Eo0

Holography for rotating black holes in $f(T)$ gravity
Masoud Ghezelbash 1308

Infinitely degenerate exact Ricci-flat solutions in $f(R)$ gravity
Semin Xavier, Jose Mathew and S. Shankaranarayanan 1319

Universe in a black hole with spin and torsion
Nikodem Popławski 1327

Asymptotically flat black hole solution in modified gravity
Surajit Kalita and Banibrata Mukhopadhyay 1337

Shadow of a charged black hole surrounded by an anisotropic matter field
Javier Badía and Ernesto F. Eiroa 1343

Constraining modified gravity theories with physical black holes
Sebastian Murk 1351

Penrose suggestion as to pre-Planck-era black holes showing up in present universe data sets discussed, with a possible candidate as to GW radiation which may provide initial CMBR data
A. W. Beckwith 1359

Summary of the parallel session BH3
Kamal Hajian and Jutta Kunz 1372

Binaries

• **Explosive Events Associated with Compact-Object Binary Mergers**
Chairpersons: Chris Belczynski and Jorge Rueda

YouTube links: https://youtu.be/Dwq1ZU3gKrg
https://youtu.be/nw02ylI6R2M

Uncertainties in kilonova modeling
C. L. Fryer, C. J. Fontes, O. Korobkin et al. 1391

• **Post-Newtonian and Post-Minkowskian Corrections for Binary Gravitating Systems**
Chairperson: Johannes Bluemlein

YouTube link: https://youtu.be/wfiLG5r08yE

Tutti-Frutti method: Recent developments in the PN/PM/SF treatment of the gravitational two-body problem
Donato Bini and Andrea Geralico 1405

• **Multichannel Studies of Nonstationary Relativistic Stars**
Chairperson: Vladimir Lipunov

YouTube link: https://youtu.be/usn2PlU_qFA

GRB observations on cubesate satellites in the Universat–SOCRAT project
Sergey I. Svertilov, Michail I. Panasyuk, Vitaly V. Bogomolov et al. 1412

Multiwavelength observations of GRB160625B by MASTER, Lomonosov, Konus-Wind and three stage collapse
V. M. Lipunov, V. A. Sadovnichy, M. I. Panasyuk et al. 1429

The role of the magnetic fields in GRB outflows
N. Jordana-Mitjans, C. G. Mundell, S. Kobayashi et al. 1449

MASTER optical observations of the blazar TXS0506+056 during the IC170922A
V. M. Lipunov, K. Zhirkov, V. G. Kornilov et al. 1467

Boson Stars

• Scalar Fields in Cosmology
Chairpersons: Carlos Herdeiro and Alfredo Macias

YouTube links: https://youtu.be/SyLoguueGKk
https://youtu.be/f9nuo8Jvw-w

A short review on nonlinear perturbation theory of structure formation for modified gravity
Jorge L. Cervantes-Cota and Alejandro Aviles 1474

Testing modified gravity theories with marked statistics
Alejandro Aviles 1494

Dark matter as condensed phase of generic bosons
Elías Castellanos and Jorge Mastache 1513

Cosmic Microwave Background

• Cosmic Backgrounds from Radio to Far-IR
Chairperson: Carlo Burigana

YouTube link: https://youtu.be/4e3Cj5wahck

New Planck tSZ map and its cosmological analysis
H. Tanimura, M. Douspis and N. Aghanim 1527

The CMB dipole: Eppur si muove
R. M. Sullivan and D. Scott 1532

High angular resolution Sunyaev Zel'dovich observations: The case of MISTRAL
E. S. Battistelli, E. Barbavara, P. de Bernardis et al. 1542

Cosmological and astrophysical results exploiting magnification bias with high-z sub-millimetre galaxies
L. Bonavera, M. M. Cueli and J. Gonzalez-Nuevo 1557

The impact of the Lorentz symmetry violation on the CMB polarization
Seddigheh Tizchang, Rohoollah Mohammadi and She-Sheng Xue 1571

Cosmic backgrounds from the radio to the far-infrared: Recent results and perspectives from cosmological and astrophysical surveys
Carlo Burigana, Elia Sefano Battistelli, Laura Bonavera et al. 1579

• **New Horizons in Cosmology with CMB Spectral Distortions**
Chairpersons: Jens Chluba and Andrea Ravenni

YouTube links: https://youtu.be/uBYLO4Smw3o
https://youtu.be/5oAPfzAe35k

CMB μT cross-correlations as a probe of PBH scenarios
Ogan Özsoy and Gianmassimo Tasinato 1609

Theoretical and numerical aspects of CMB spectral distortions from non-thermal energy injections
Sandeep Kumar Acharya, Jens Chluba and Abir Sarkar 1628

BISOU: A balloon project to measure the CMB spectral distortions
B. Maffei, M. H. Abitbol, N. Aghanim et al. 1633

Cosmic microwave background spectral distortions constraints on decaying dark matter particles and axion-like particles using *COBE/FIRAS* and *EDGES*
Boris Bolliet 1645

The COSmic Monopole Observer (COSMO)
S. Masi, E. Battistelli, P. de Bernardis et al. 1654

• **Status of the $\mathbf{H_0}$ and $\boldsymbol{\sigma_8}$ Tensions: Theoretical Models and Model-Independent Constraints**
Chairpersons: Joan Solà Peracaula and Adrià Gómez-Valent

YouTube links: https://youtu.be/VNWZ1Bzjus4
https://youtu.be/zEBOCwvetKE
https://youtu.be/nzgC7qV9H_Y

Measuring the Hubble constant H_0 from gravitational lensing
Liliya L. R. Williams 1672

Extra components consistency in the Hubble tension and BBN
Osamu Seto and Yo Toda 1686

Gravitational anomalies, axions and a string-inspired running vacuum model in Cosmology
Nick E. Mavromatos 1693

Early and not so early dark energy. What do cosmological observations tell us about them?
Adrià Gómez-Valent, Ziyang Zheng, Luca Amendola, Valeria Pettorino and Christof Wetterich 1713

Renormalized $\rho_{\rm vac}$ without m^4 terms
Cristian Moreno-Pulido and Joan Solà Peracaula 1733

BD-ΛCDM and running vacuum models: Theoretical background and current observational status
Javier de Cruz Pérez, Joan Solà Peracaula, Adrià Gómez-Valent and Cristian Moreno-Pulido 1752

Cosmological tensions: Hints for a new concordance model?
E. Di Valentino 1770

Solving both H_0 and σ_8 tensions in $f(T)$ gravity
Emmanuel N. Saridakis 1783

Precision Cosmology and Hubble tension in the era of LSS surveys
G. Fanizza 1792

• **Effects of Primordial Perturbations Enhancement: From Black Holes Formation to CMB Anomalies**
Chairpersons: Antonio Enea Romano and Krzysztof Turzynski
YouTube link: https://youtu.be/frjjONXbd1M

Primordial black holes arise when the inflaton falls
Keisuke Inomata 1803

Effects of the modification of gravity on the production of primordial black holes
Sergio Andrés Vallejo Peña 1809

Cosmic Strings

• **Cosmic Strings**
Chairpersons: Reinoud Jan Slagter and Batool Imtiaz
YouTube link: https://youtu.be/ZpaU82ZUHzM

$U(1)$ local strings in generalized hybrid metric-Palatini gravity
Hilberto M. R. da Silva, Tiberiu Harko, Francisco S. N. Lobo and João Luís Rosa 1820

New evidence of the azimuthal alignment of quasars spin vector in Large Quasar Groups and cosmic strings
R. J. Slagter 1835

Summary parallel session cosmic strings I
Reinoud Jan Slagter and Batool Imtiaz 1848

• **From Cosmic Strings to Superstrings**
Chairpersons: Carlos Martins and Ivan Rybak
YouTube link: https://youtu.be/LJFtV_4aSAg

Scaling solutions of wiggly cosmic strings
A. R. R. Almeida and C. J. A. P. Martins 1851

High resolution calibration of string network evolution
J. R. C. C. C. Correia and C. J. A. P. Martins 1871

Radiation from Global Cosmic Strings using adaptive mesh refinement
Amelia Drew and E. P. S. Shellard 1891

Analysing the scaling density of axion strings
A. Lopez-Eiguren 1898

Electroweak axion string and superconductivity
Yu Hamada, Yoshihiko Abe and Koichi Yoshioka 1912

Dark Energy and Large Scale Structure

• **Dark Energy and the Accelerating Universe**
Chairpersons: Alexei Starobinky and David Polarski
YouTube links: https://youtu.be/JZEPRS_rqbE
https://youtu.be/3aG_AT4UzWE
https://youtu.be/ZlTWquG-pFk

Hints for the $H_0 - r_d$ tension in uncorrelated Baryon Acoustic Oscillations dataset
Denitsa Staicova 1923

Observational constraints on nonlinear matter extensions of general relativity
E.-A. Kolonia and C. J. A. P. Martins 1935

Constraining the dark energy-dark matter interaction model using low-redshift observations
Archana Sangwan, Joseph P. J. and S. Shankaranarayanan 1948

On the evolution of inhomogeneous perturbations in the ΛCDM model and $f(R)$ modified gravity theories
T. Schiavone and G. Montani 1961

Soft dark energy and soft dark matter
Emmanuel N. Saridakis 1970

A simple parametrisation for coupled dark energy
Vitor da Fonseca, Nelson J. Nunes and Tiago Barreiro 1979

• **Cosmography with Gravitational Lensing**
Chairpersons: Claudio Grillo and Mimoza Hafizi
YouTube link: https://youtu.be/FXplIAvUDBM

A tale of two double quasars: Hubble constant tension or biases?
L. J. Goicoechea and V. N. Shalyapin 1990

Dark Matter

• **Interacting Dark Matter**
Chairpersons: Nikolaos Mavromatos
YouTube links: https://youtu.be/zOshKJlwD-Y
https://youtu.be/JR44dh2GYik

Dark energy and dark matter unification from dynamical space time: BBN constraints
D. Benisty 2005

Entropy and irreversible processes in gravity and cosmology
Llorenç Espinosa-Portalés and Juan García-Bellido 2013

LHC experiments for long-lived particles of the dark sector
Vasiliki A. Mitsou 2029

Constraining the interactions in the dark sector with cosmological data
Adrià Gómez-Valent, Valeria Pettorino and Luca Amendola 2050

Running vacuum interacting with dark matter or with running gravitational coupling. Phenomenological implications
Joan Solà Peracaula 2069

Dark matter properties from the Fornax globular cluster timing: Dynamical friction and cored profiles
D. Blas 2089

Growth of linear perturbations in a universe with superfluid dark matter
S. Banerjee, S. Bera and D. F. Mota 2101

Interacting dark sector in the late Universe: Mapping fields and fluids, and observational signatures
Joseph P. J. and S. Shankaranarayanan 2119

The role of self interactions in the cosmological evolution of warm dark matter
R. Yunis, C. R. Argüelles, D. López Nacir et al. 2127

Interaction energy between a charged medium and its electromagnetic field as a dark matter candidate
Mayeul Arminjon 2139

• Dark Matter Searches with Liquid Xenon and Argon Detectors and Self Gravitating Systems and Dark Matter
Chairpersons: Marco Merafina and Soroush Shakeri and She-Sheng Xue

YouTube link: https://youtu.be/H9oGYnGq9pI

The maximum mass of dilute axion stars
Pierre-Henri Chavanis 2149

A dark matter solution for the XENON1T electron excess and the galactic center 511 keV line
Yasaman Farzan 2174

Preliminary results of rich galaxy clusters' spatial distribution analysis on CfA2 Redshift Survey data: Compact objects or dark matter presence at redshift less 0.032
I. V. Arkhangelskaja, A. M. Galper, L. N. Khanh and D. N. Dorosheva 2189

• Dark Matter: Beyond ΛCDM
Chairpersons: Carlos Argüelles and Andreas Krut

YouTube links: https://youtu.be/hdKeo5L7pYE
https://youtu.be/i0IPHXzmV-s

Probing the nature of dark matter with Milky Way subhaloes
M. R. Lovell 2202

Addressing classical cosmological back-reaction with multiple scales
Yonadav Barry Ginat 2217

Imaging formation process for DM profiles
Omar de J. Cabrera-Rosas and Tonatiuh Matos 2222

The self-gravitating Fermi gas in Newtonian gravity and general relativity
Pierre-Henri Chavanis 2230

• Dark Matter and Rare Processes
Chairpersons: Rita Bernabei and Zurab Berezhiani

YouTube links: https://youtu.be/wheVrbETP_0
https://youtu.be/dVdZ4TIDxt0

The dark matter: DAMA/LIBRA and its perspectives
R. Bernabei, P. Belli, V. Caracciolo et al. 2252

Dark matter directionality approach
R. Bernabei, P. Belli, V. Caracciolo et al. 2272

Collapse models under test by high sensitivity γ-ray and X-ray measurements
C. Curceanu, Kristian Piscicchia, Massimiliano Bazzi et al. 2288

Leptophilic dark matter at linear colliders
P. S. Bhupal Dev 2296

DM6 session: Dark matter and rare processes
R. Bernabei and Z. Berezhiani 2316

• **The Nature of Galactic Halos**
Chairpersons: Francesco De Paolis and Asghar Qadir
YouTube link: https://youtu.be/qIwVnNxi0n0

Primordial black holes as dark matter candidates in the Galactic halo
Lindita Hamolli, Mimoza Hafizi, Francesco De Paolis and Achille A. Nucita 2319

Giant cosmic ray halos around M31 and the Milky Way
S. Recchia, S. Gabici, F. A. Aharonian and V. Niro 2335

A nearly complete census of intergalactic gas using the kinematic Sunyaev-Zel'dovich effect
Chaves-Montero, Jonás 2345

Searching for Intermediate Mass Black Holes in the Milky Way's galactic halo
A. Franco, A. A. Nucita, F. De Paolis, F. Strafella and M. Maiorano . . . 2352

Virial clouds evolution from the last scattering up to the formation of first stars
Noraiz Tahir, Asghar Qadir, Muhammad Sakhi and Francesco De Paolis 2360

Testing Weyl-modified gravity on M31 and Milky Way
Muhammad Bilal and Asghar Qadir 2365

PART C

Education

• **Teaching Einsteinian Physics to School Students**
Chairpersons: David Blair and Matteo Luca Ruggiero
YouTube links: https://youtu.be/W-WV6J8kprg
https://youtu.be/UHYpwKQ09SU

Teaching relativity: A paradigm change
F. Herrmann and M. Pohlig 2371

Teaching relativity: Computer-aided modeling
F. Herrmann and M. Pohlig 2381

Solstices and Equinoxes in 1703 at the meridian line of St. Maria degli Angeli in Rome, and the stellar aberration of Sirius
Costantino Sigismondi and Silvia Pietroni 2388

Positional astrometry at arcsecond accuracy using historical instruments, with light equipment
Costantino Sigismondi and Lorenzo Ricciardi 2398

Daily, seasonal, and equinoctial solar paths on a school soccer field
Costantino Sigismondi 2411

Teaching relativity at the AstroCamp
C. J. A. P. Martins 2415

Sungrazing comets as General Relativistic gravitational probes
Silvia Pietroni and Costantino Sigismondi 2424

The three Summer solstice's markers of 1721 unveiled in the Basilica of Santa Maria degli Angeli in Rome
Costantino Sigismondi 2428

Einstein-First: Bringing children our best understanding of reality
A. Popkova, K. Adams, S. Boublil et al. 2438

Exact Solutions

• **Exact Solutions in Four and Higher Dimensions**
Chairpersons: David Blair and Matteo Luca Ruggiero

YouTube link: https://youtu.be/GHZUS5-4gVQ

Kundt spacetimes in the Einstein–Gauss–Bonnet theory
R. Švarc, J. Podolský and O. Hruška 2453

Exact decoupled solutions in curvature-matter coupled gravity
M. Sharif and Fizza Furqan 2464

Tolman-Oppenheimer-Volkov conditions beyond spherical symmetry
José P. Mimoso, Alan Maciel and Morgan Le Delliou 2479

A spherically symmetric stiff fluid spacetime in light of cosmic structure formation
Daniele Gregoris 2497

• **Exact Solutions (Including Higher Dimensions)**
Chairperson: Susan Scott

YouTube link: https://youtu.be/-hJjJvmmOew

Three-parameter solution for the null-surface formulation in 2+1 dimensions
Tina A. Harriott and J. G. Williams 2510

New exact stationary cylindrical anisotropic fluid solution of GR
M.-N. Célérier 2522

Early Universe

• **Quantum Fields**
Chairperson: Andrei Lebed

YouTube links: https://youtu.be/BLaTp0r0TkQ
https://youtu.be/ZifgaSDy5Vc

Hydrodynamic representation and energy balance for the Dirac and Weyl fermions in curved space-times
Tonatiuh Matos, Omar Gallegos and Pierre-Henri Chavanis 2533

Breakdown of the Equivalence Principle for a composite quantum body
A. G. Lebed 2551

Extended DeWitt-Schwinger subtraction scheme, heavy fields and decoupling
Antonio Ferreiro and Jose Navarro-Salas 2557

Renormalization and decoupling for the Yukawa model in curved spacetime
Sergi Nadal-Gisbert, Antonio Ferreiro and José Navarro-Salas 2562

Trace anomaly and evaporation of spherical black holes
P. Meda 2573

On decay of the false Unruh vacuum
A. Shkerin 2587

Behaviour of noise kernel in de Sitter and FRW space-times
Ankit Dhanuka and Kinjalk Lochan 2600

Breaking Buchdahl: Ultracompact stars in semiclassical gravity
Julio Arrechea, Carlos Barceló, Raúl Carballo-Rubio and Luis J. Garay 2608

Einstein anomaly with tensors of odd order in six dimensional curved space
Kohei Yamamoto and Satoshi Yajima 2619

Quantum memory and BMS symmetries
Sanved Kolekar and Jorma Louko 2623

• Topological Methods, Global Existence Problems, and Spacetime Singularities
Chairperson: Spiros Cotsakis

YouTube link: https://youtu.be/H8Itnc_C10c

Gravitational singularities, scattering maps for bouncing, and structure-preserving algorithms
Philippe G. LeFloch 2630

Brane-world asymptotics in a nonlinear fluid bulk
I. Antoniadis, S. Cotsakis and Ifigeneia Klaoudatou 2645

Primordial synchronization of Mixmaster spatial points
Spiros Cotsakis 2657

• The Early Universe
Chairperson: Stefano Ansoldi

YouTube links: https://youtu.be/m80hHWgOlFs
https://youtu.be/6tyaZ8MMVtw

Quintessential inflation from Lorentzian slow roll
David Benisty 2663

Condensed light, quantum black holes and L-CDM cosmology: Experimentally suggested and tested unified approach to dark matter, dark energy, cosmogenesis and two-stage inflation
Victor Borsevici 2672

Helical magnetic fields lead to baryogenesis
Ashu Kushwaha and S. Shankaranarayanan 2692

Polymer Quantization of the Isotropic Universe: Comparison with the Bounce of Loop Quantum Cosmology
G. Barca, E. Giovannetti, F. Mandini and G. Montani 2700

General relativistic evolution equations for density perturbations in open, flat and closed FLRW universes and the problem of structure formation
Pieter G. Miedema 2708

Constraining beyond ΛCDM models with 21cm intensity mapping forecast observations combined with latest CMB data
M. Berti 2726

Entropy and irreversible processes in gravity and cosmology
Llorenç Espinosa-Portalés and Juan García-Bellido 2737

Fundamental Interactions and Stellar Evolution

• Why and How the Sun and the Stars Shine: The Borexino Experiment
Chairpersons: Giampaolo Bellini, Dmitry Naumov, Gioacchino Ranucci, Gemma Testera

YouTube links: https://youtu.be/hh5wDnM8miU
https://youtu.be/TG-HgBf7W4s
https://youtu.be/HLiis2LFeEs

Experimental detection of the CNO cycle
B. Caccianiga, N. Rossi, G. Testera et al. 2753

Borexino detector performances
A. Caminata, M. Agostini, K. Altenmüller et al. 2765

Study of antineutrinos from the Earth and the Cosmos with the Borexino detector
Sandra Zavatarelli, M. Agostini, K. Altenmuller et al. 2774

Unveiling the engine of the Sun: Measurements of the *pp*-chain solar neutrinos with Borexino
D. Guffanti, A. C. Re and O. Smirnov 2785

Electron neutrino survival probability in the energy range 200 keV–15 MeV
Marco Pallavicini on behalf of the Borexino Collaboration 2804

The relevance of pp-chain and CNO-cycle neutrino measurements for solar physics
F. L. Villante and A. M. Serenelli 2815

Role of the CNO cycles in stars
A. Ianni 2835

Geoneutrino observation
Tadao Mitsui for the KamLAND Collaboration 2840

Synthesis of the session: Why and how the Sun and the stars shine
Gianpaolo Bellini 2845

The observation of the stars in daytime and near the horizon

Costantino Sigismondi
ICRA, Sapienza University of Rome,
Rome, Italy
E-mail: sigismondi@icra.it
www.icra.it/solar

Paolo Ochner
Padova University and Asiago Astrophysical Observatory, Italy

Traditionally when a star was near the solar conjunction, its magnitude was not measured from groundbased observations. In this way the lightcurves of variable stars show yearly gaps of about two or three months each year. Some observations made in twilight and in daytime in Rome of Betelgeuse, Antares and Venus are described.

Keywords: Atmospheric seeing, Airmass extinction, Daytime astronomical observations of stars.

1. Introduction: Betelgeuse and its 2020 secondary minimum

On 31 march 2020 Betelgeuse's luminosity was again in its rising phase, after the deep minimum Worldwide discussed. The observations of this phase continued in the evening until April 2020, on a dark sky. By the end of April the star was entering in twilight visibility for Rome, and its luminosity measurement with Argelander's method become complicate. The sky background rised, and the Purkinje effect affected the perception of the stellar luminosity by naked eye. Moreover the airmass' extinction near the horizon is affected by the humidity, which is a variable effect with the season and with the meteorological local conditions. Air turbulence also complicates the signal to noise ratio of the star. The cases of Antares at the meridian at 21° of altitude at sunset and of Venus at the meridian in afternoon, both observed in Vatican, are also discussed.

2. Sky background, airmass and comparison stars

A bright star is visible through a telescope during the day, the conditions required are: clear sky and exact pointing. For Betelgeuse in twilight, near the Western horizon in end of May in Rome, a dried tree in the foreground was used to aim at the star's position with a monocular or a small Newtonian telescope of 76 mm mirror.

For measuring the stellar magnitude the usual comparisons stars were not visible: Aldebaran, red as Betelgeuse, was already set and Procyon, white and normally

brighter than Betelgeuse, was not visible neither close to a landmark. Only Mercury, reddish, was bright and low enough to be seen and compared. γ Geminorum, white, also was detectable close to Betelgeuse and to another landmark.

These conditions allowed to verify that a "regular" $1/\sin$ cosecant law for the airmass extinction does not apply for the evening horizon in may in Rome.

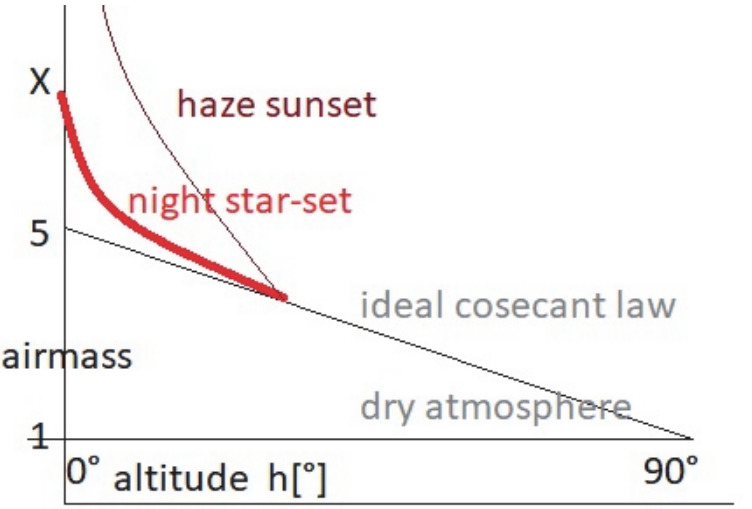

Fig. 1. Airmass extinction in dry atmosphere, night star set and haze sunset (as in end of August, in Rome). The deviation from the cosecant law are relevant below 15°.

Other experiences with sea sunsets showed strong departures from the cosecant law near the horizon in presence of humidity: the solar light can be extinct by an equivalent up to 30 airmasses of haze, or only by 5 airmasses in drier days. In the former situation the lower limb of the Sun disappears before reaching the horizon, while in the latter the Sun remains bright until the last glimpse of light.

2.1. *Atmospheric seeing*

Air turbulence is stronger in daytime, and large bubbles of hot air from locations close to the observer defocus the star. This fact complicates the visibility of the star on a bright sky background. Antares at the meridian, at 21° of altitude at sunset on 21 August 2021 was visible less than 50% of the duration of the observation, continuously disappearing and reappearing without having changed the focus of the telescope 10×42; only Venus, under clear sky, appeared steadily visible in daytime, through a monocular 7x18 on October 5, 2021. In other days of October 2021 the defocus affected also the observation of Venus.

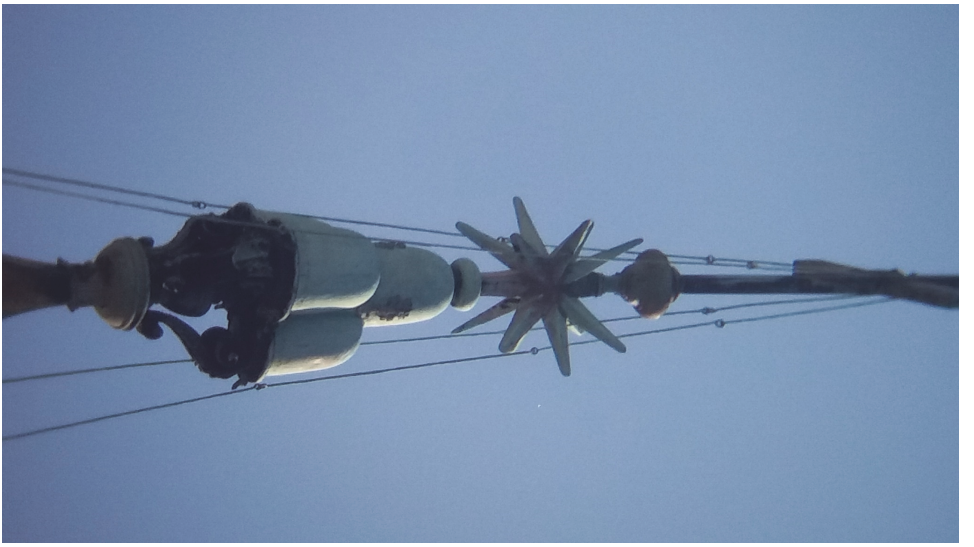

Fig. 2. A photo of Venus in daytime on October 5, 2021 at 16:10 local time, with the top of st. Peter's Obelisk in Vatican. In this photo Venus is below the center of the tridimensional star, as a bright point on the blue sky.

3. The early morning reappearances of Betelgeuse in September

My observations of Betelgeuse made in September from 2012 to 2021, and in general the first observations after the solar conjunction, showed a systematic increase of the perceived luminosity. Aldebaran, Procyon and Rigel are always used as comparison stars, and the airmass correction was carefully considered. The detector is my eye, and this systematic luminosity increasing, can be due to a physiological effect like the Purkinje's one, even if I applied the recommendation of not staring at the star. *Exempli gratia* on September 15, 2021 a careful observation, with the star "bracketed" with Aldebaran and Procyon and Rigel, yielded magnitude 0.27, 0.25 magnitudes brighter than V-band observations in AAVSO database for the same days. Moreover this luminosity is brighter than average maxima of Betelgeuse, which was nearly at the meridian on a starting twilight phase. Other September's luminous cases have to be attributed to the heavy haze at the Eastern horizon: either facing the Adriatic sea in Lanciano (265 m above sea level), either from the Asiago highland (1000 m). The clearness of the morning sky, and the low humidity dispersed in the atmosphere can be the responsible of such peculiar situation.

3.1. *Recovering airmass on the AAVSO-SGQ observations' catalogue*

The airmass of Betelgeuse during all these particular observations in September ranges from 2 to 3, and can be calculated on AAVSO-SGQ catalogue by selecting

SGQ as observer, in searching Alf Ori observations (and all the other variable stars observed).

The location of the observation is always reported in the notes, and the time is required by the application form. So the data for recomputing the airmass are made available.

4. Conclusions

The Argelander's method consists to bracket the luminosity of the star in study among two comparison stars. For Betelgeuse it is necessary to apply always the airmass corrections, because the angular distance of the comparison stars, usually Aldebaran and Procyon, produce artificial difference in luminosity.

The airmass correction can depart from the cosecant law near the horizon due to the haze (fig. 1).

Defocus effects of the air turbulence complicate this measurement. From Rome the magnitude of Betelgeuse has been measured as late as 31 May, in 2021. From the southern hemisphere in Australia Rod Stubbings could observe until the same date in 2021 and until 10 of June in 2020.

From Brasil, Florianopolis, Alexandre Amorim could observe from 8 July in the morning twilight.

The observations in V-band of Otmar Nickel were performed in daytime, during the solar conjunction, allowing a ungapped monitoring of the luminosity of this star.

Padova University and Asiago Astrophysical Observatory, Italy

The occurrence of the deep minimum of Betelgeuse in 2020 has been object of a Worldwide debate, mainly on the public media. The session dedicated to Betelgeuse in the XVI Marcel Grossmann Meeting focused the many aspects of this debate, offering a good state of art of this subject, after and during an unprecedented observational effort from ground, airborne and from the space.

Keywords: Betelgeuse; Red giant; Variable stars.

1. Betelgeuse among the red giant variable stars

The special session HR1 *History of Relativity I* of the XVI Marcel Grossmann Meeting was dedicated to the Great Dimming of Betelgeuse, occurred from December 2019 to February 2020. This meeting gathered prominent scholars in this research field, and relevant representatives of the amateur astronomers who participated to the observational campaign of Betelgeuse (Wolfgang Vollmann from Vienna and Rod Stubbings from Australia).

The impact of Betelgeuse's dimming in the media, last year, is an index of how such an astronomical phenomenon can drive interest of the great public, and for how long, and why. One of the most recurrent issues was the supernova ending of its stellar history (because it was believed or announced to be imminent, as a consequence of the three months dimming... and this common mistake in the press, even specialized, was the reason why Relativistic Astrophysicists decided to clarify the nature of a potential gravitational collapse). Pre-supernova stages of supergiants are very poorly known, even for SN 1987A (Massimo Turatto, 2020 ICRANet Betelgeuse meeting), but a core-collapse event lasts only an hour, as recalled in the plenary session of this meeting (Chris Fryer).

In any case Betelgeuse ranks among the ten brightest stars in the sky, and it is variable, with amplitudes normally around 0.5 magnitudes from minimum to maximum, which become 1.0 magnitudes for the Great Dimming of 2020.

2. Observing Betelgeuse, the culture of mankind, and the didactic

Betelgeuse is part of the night sky culture of mankind, probably documented since Lascaux caves in the Pyrenees (Cro-Magnon civilization, 40000 years ago) and present in Greek mythology. Its dimming in 2020 has excited again the human fantasy, as well as an unprecedented observational campaign in all part of the spectrum.

Fig. 1. The Lascaux painting in the cave. The Taurus, at top center, is probably an Urus (Bos Primigenius). From this general view the detail of astronomical interest is shown below.

Fig. 2. The detail where Orion would appear. The Pleiades are also identified, Orion's belt is four point aligned in the previous global image. Andrea Dupree drawn our attention to this document.

This variability can be followed potentially by all, by applying some basic airmass correction to the reference stars and Betelgeuse itself (Costantino Sigismondi and Tiziana Pompa) even in twilight. The natural continuation of this approach, which is also didactic, is the daylight observations of Betelgeuse from ground, by Otmar Nickel, used to integrate the V and visual light curve of Betelgeuse obtained with the dark night sky. The search of peculiarities of "the painful shoulder"[4] of Orion is a natural way to approach this phenomenon, while the modern data on Betelgeuse magnitudes is less than two centuries (Sir John Herschel in 1837-41). How different is Betelgeuse from Antares and other red supergiant stars? In the timescales of stellar evolution how peculiar was this dimming? This provocation came from Jacco van Loon, the chairman of GAPS 2021, a 254-participants online meeting held in June 2021 on Red Supergiants.

3. Date of this meeting among the light curve of Betelgeuse

The date of this meeting occurred after a whole pulsational period (425 days) from the Great Minimum dated around 11 February 2020. This was the occasion to compare the Great Minimum with the following one, in order to verify the uniqueness of the 2020 event, or, conversely, its statistical fluctuation's nature. The light curves presented at this parallel session were all updated to the day before, thanks to the daytime and spacebased observations.

4. Time series analysis issues in the lightcurve of Betelgeuse

The time-series analysis of the light curve of Betelgeuse, to identify possible signatures of changes in the nature of the physical pulsations, has been the subject treated by Sandip V. George. The issue of new oscillation regime with period shorter than the main one of 425 days, seemed to appear from the preliminary light curves presented by Edward Guinan and Andrea K. Dupree: they exploited satellite and groundbased daytime measurements to follow the luminosity of the star during the months of solar conjunction.

5. ID card of Betelgeuse

The stellar parameters of Betelgeuse have been investigated in depth by Meridith Joyce by comparing observational data with synthetic data obtained with the best program of stellar evolution simulation, MESA. Mass, radius and distance have been reconsidered with this technique, while the measurements with astrometric satellites (from Hipparcos to GAIA) are affected by the asymmetry of the stellar surface of Betelgeuse. The opportunity to consider a recent merging history with a smaller companion was part of the presentation of Alexey Bobrick, concerning the dynamical history of Betelgeuse. The opportunity to observe Betelgeuse in the mid-infrared part of the spectrum from the stratosphere was presented by Graham

Harper, who showed that the variation of temperature on the photosphere of Betelgeuse, might be responsible for the dimming, more than "dust eclipses" produced by material ejections along the line of sight. Higher spatial resolution images obtained with the Hubble Space Telescope are confirming this issue, and the great hot and cold spots on the surface of the star are reflecting the convective cells on this supergiant, as the presentations of Edward Guinan and Andrea Dupree have shown from various perspectives.

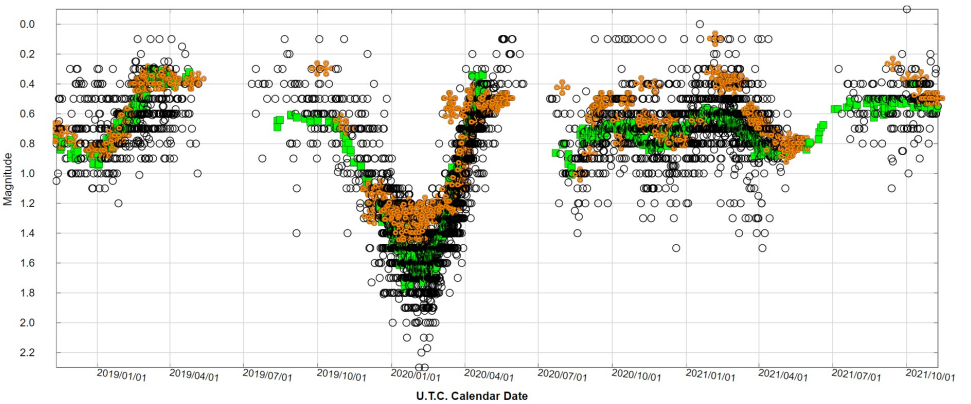

Fig. 3. The AAVSO light curve of Betelgeuse in the last three years (November 2018-2021). Evidenced in orange cross are 310 visual observations of the author. Note the green data in V-band during the Summer of 2021, by Otmar Nickel: they firstly cover completely the yearly gap during the solar conjunction. The visual data in the Summer 2020 are of Rod Stubbings from near Melbourne, Alexandre Amorim from Florianopolis and myself from Rome till end of May. The other V-band green data: 458 are of Wolfgang Vollmann who follows Betelgesue since 1976.

6. Perspectives

This session, held on July 8th, 2021, can be a reference for future studies on Betelgeuse and Red Giants in general, as well as an ideal introductory event to modern stellar variability, from naked eye observations to stellar interferometry techniques to airborne and space telescopes and satellite observations. The goal of having a good state-of-art meeting about Betelgeuse, its astrophysics and its observations, has been obtained.

Photometry of Betelgeuse at daylight

Otmar Nickel
zum Schollberg 11, 55129 Mainz, Germany
E-mail: otmar.nickel@web.de

In a backyard observatory in Mainz, Germany, several stars have been observed at daylight using a 250mm Newton telescope and a CCD camera. The sky background was measured on several days; values of 1.8 - 4.7 mag/arcsec2 were found at angles of 10°-100° distance to the Sun. Photometry of Betelgeuse was performed as a first attempt in 2020 with stacked images of Betelgeuse; it was improved in 2021 by using a neutral density filter (1 percent transmission) and measuring calibration and extinction coefficients on 4-8 bright reference stars. Photometry of Betelgeuse resulted in calculated errors of less than 0.05 mag from February to July 2021. It could be shown, that daylight observations of Betelgeuse can fill the observational gap with reliable magnitude data, when Betelgeuse is near to the Sun.

Keywords: Betelgeuse, photometry

1. Overview

Fig. 1 shows a light curve of Betelgeuse in the V-band, taken by many amateur astronomers with digital cameras (Kafka S, 2021). Unfortunately there are gaps in this curve, when Betelgeuse is near to the Sun, that means at a distance of less than about 30°. To fill these gaps there are 3 ways:
- Observations in twilight close to horizon (preferable in the southern hemisphere)
- Observations with space probes distant from earth (e.g. STEREO-A)
- Observations at daylight
In this paper I will report about daylight observations of Betelgeuse, which I have done this and the last year.

2. Equipment

The telescope of my observatory is a Newtonian telescope with 250 mm aperture on an equatorial mount. The mount is computer controlled with encoders in both axes. Images are acquired by a cooled CCD camera ATIK 460exm with a V filter and a neutral density filter (1 percent transmission), to reduce the light intensity. The camera is capable of exposures down to 1 ms. The front of the tube is prolonged with a cylindrical shade to reduce stray light from the Sun.

3. Sky brightness

The sky brightness can be measured in magnitudes per square arcsec; fig. 2 shows own measurements from 17 cloudless days (July to September 2020 and February to

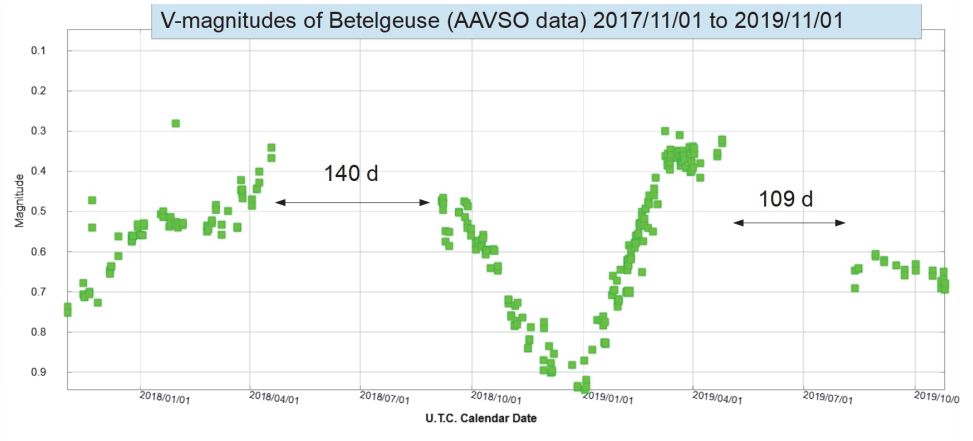

Fig. 1. Light curve of Betelgeuse 2017/11 to 2019/11 (AAVSO data)

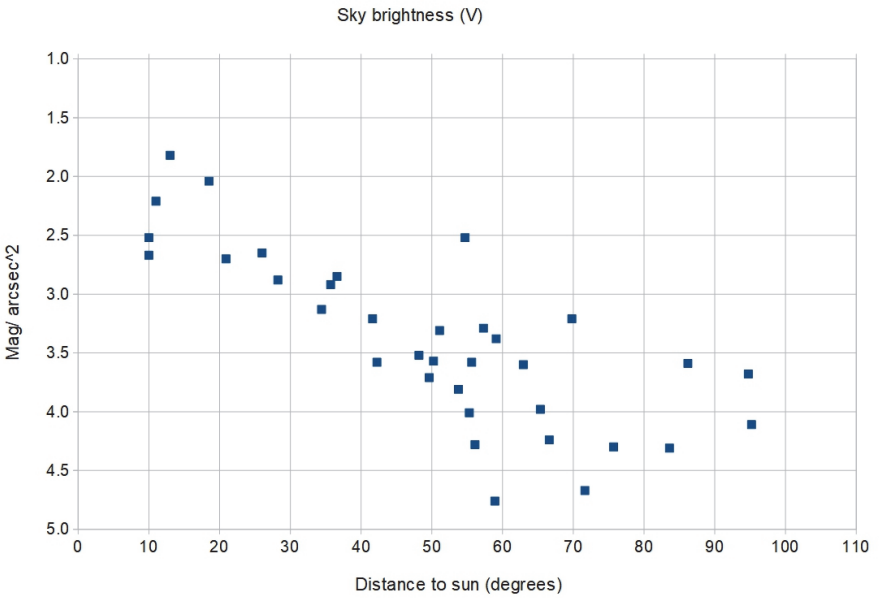

Fig. 2. Measured sky brightness versus solar angular distance

April 2021) at my observatory as graph. The sky brightness depends mainly on the angular distance to the Sun (which is shown here on the horizontal axis). Between 60 and 100 degrees the sky brightness seems to be stable, but here the scattering of data is very high, because other parameters (e.g. airmass and humidity) have more

influence. It can be shown, that stars can be imaged with reasonable signal-to-noise ratio, if their brightness in magnitudes is at least in the order of the sky brightness in mag per square arcsec. Therefore stars up to 2 magnitudes could be observed near to the Sun.

4. Methods

To get images of a star at daytime with a reasonable signal-to-noise ratio, one has to record a large number of images with short exposure time and to add them together to a "stacked" image, as seen in fig. 3.

To evaluate the brightness of a star, first an instrumental magnitude has to be processed, which is proportional to the logarithm of pixel counts corrected by the sky background. The same procedure is done for one or more stars, whose magnitude is known to get a standardized magnitude by comparison.

I did first measurements of Betelgeuse (in 2020) with only 1 comparison star, namely Aldebaran (alpha Tau). To get the correct magnitude, it is necessary, to measure also the extinction of all stars used for the comparison. Therefore the method was improved in 2021 by using an ensemble of 4-8 reference stars with brightness of up to 2 magnitudes and measuring the extinction constant.

The standard magnitude V_{var} can be calculated by the following equation (Da Costa GS, 1992):

$$V_{var} = m_{inst} + T_v(B-V)_{var} + m_0 - k_v X_{var} \tag{1}$$

where

m_{inst} = instrumental magnitude of variable
T_v = color transformation constant for V-Band
$(B-V)_{var}$ = color index of variable
m_0 = zero point (depending on sensitivity of the system)
k_v = extinction constant
X_{var} = airmass of the variable star

m_0 and k_v were determined for each measurement from the color corrected instrumental magnitudes of the ensemble of reference stars by linear regression.

5. Results

Fig. 4 shows the 2020 light curve of Betelgeuse with the results of my first attempts for daylight measurements (seen as crosses). The 3 red points are measurements of the STEREO-A space probe (Dupree A, et al, 2020). The errors of the daylight measurements were in the order of 0.07 mag.

Fig. 5 shows the 2021 light curve, again with my daylight measurements, seen as crosses. The gap of values could be relatively well filled with data, the errors were less than 0.05 mag, even at the closest distance of 16° to the Sun. There is a light

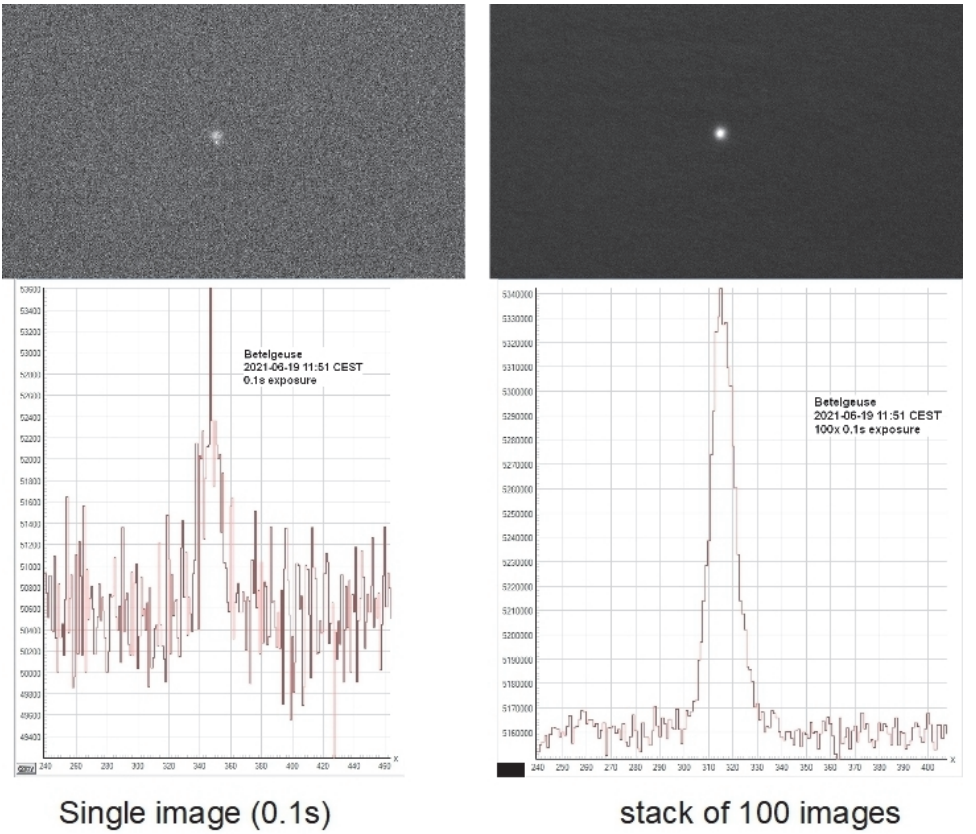

Fig. 3. Images and profiles of Betelgeuse near to sun, left: single image, right: stack of 100 images

systematic error of 0.02 magnitudes; the reason for that may be a slight error of the color transformation, which can be significant for Betelgeuse with its highly red color index.

The method was tested also on a star which comes even closer to the Sun than Betelgeuse: The V magnitude of Alpha Ari was measured on 6 days at a distance to the Sun of 35° down to 10°. The mean value of all measurements was 2.0 ±0.035, which is very close to the Hipparcos magnitude (2.01 mag).

6. Conclusions

- Measurements of the V magnitude of Betelgeuse are possible with astronomical cameras at daylight, even at closest distance to the Sun
- The method gives reliable results with an error of less than 0.05 mag (clear sky provided)

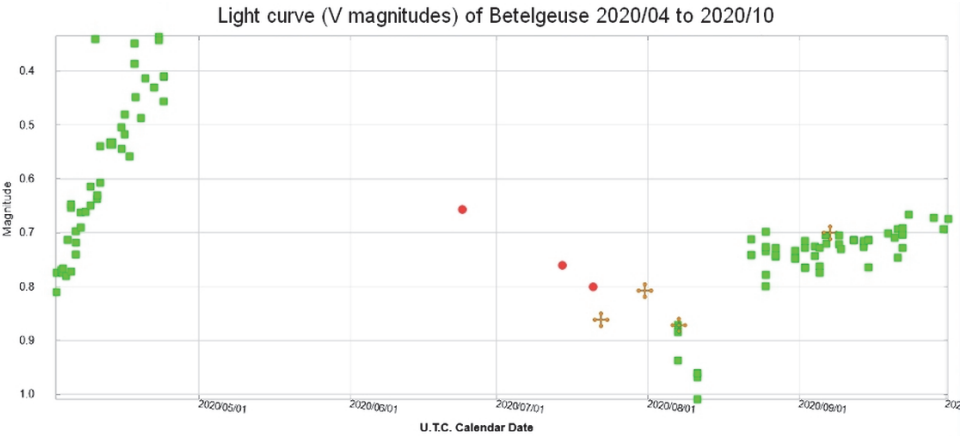

Fig. 4. Light curve of Betelgeuse 2020; green points: V mag data (AAVSO data base), crosses: daylight data, red dots: STEREO-A data

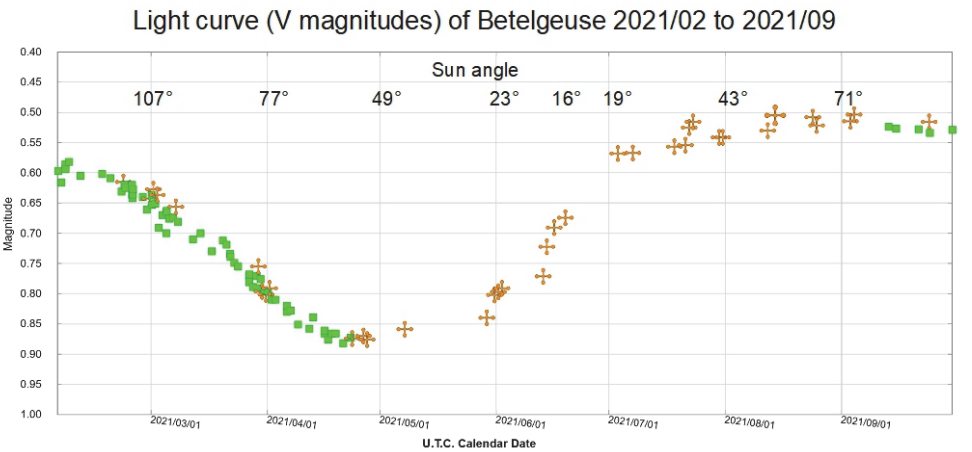

Fig. 5. Light curve of Betelgeuse 2021 (Kafka S, 2021); green points: V mag data (AAVSO data base), crosses: daylight data

- The solar conjunction gap of the light curve can be filled in the future, if the method is used also by other observers with suitable equipment.

The reasons behind the Great Dimming and subsequent rising in the brightness of Betelgeuse between October 2019 and March 2020 still continues to baffle astronomers. It has been shown by George et al. (2020) that critical slowing down preceded the dimming event. This suggested that the dimming was as a result of the change in the nature of the nonlinear dynamics of the star. In this work we present additional evidence for dynamical changes in Betelgeuse prior to the Great Dimming event, using nonlinear time series analysis. We study the relations between the different bands in the photometry data collected from the Wing photometery (IR/near-IR) and Wasatonic observatory (V-band). We also analyse how the early warning signals studied previously changed during and after the Great Dimming.

Keywords: Critical slowing down, alpha orionis, recurrence quantification analysis, wing photometry.

1. Overview

The unprecedented dimming and subsequent brightening events in Betelgeuse between October 2019 and March 2020 have since been studied in extensive detail.[1–3] Three main hypotheses have been suggested as reasons for the dimming, namely changes in pulsation dynamics, star spots and a dust cloud. Combinations of these

hypotheses have also been suggested as reasons for the dimming.[4,5] We will explore each of these explanations below, before explaining how the nonlinear dynamics of the light curve can contribute towards understanding the dimming.

The most prominent reason suggested for the Great Dimming observed in Betelgeuse has been the formation of a dust cloud. This has been put forward as an explanation by multiple authors. Measurements of effective temperature have suggested that no significant drop was observed during the dimming.[6] In addition, high angular resolution images showed a significant dimming in the southern hemisphere of Betelgeuse during the dimming event.[7] Observations from multiple wavelengths suggest that an outflow from the star itself, enhanced by pulsations, condensed around the southern hemisphere of the star.[4,5] It has also been suggested that the dimming could be explained by an ejection from the star that cools below 3000 K to form molecules, before condensing to dust.[8]

The dust hypothesis has been disputed as the sole reason for the dimming by a number of authors. Radiative transfer models using data from sub-millimeter wavelengths suggested that the dimming was a result of changes in the photosphere as opposed to external dust.[9] Further, observations during the dimming suggested that there was little change in the IR flux.[10] Moreover, Wing three-filter TiO and near-IR photometry found that the effective temperature during the dimming could be much lower than previously calculated, suggesting that the dimming observed in the visible spectrum could be due to photospheric motions.[11] Many of these authors proposed the presence of spots on the stellar surface as an alternative reason for the dimming of Betelgeuse.[9,12]

Finally, it has been suggested that the observed dimming was as a result of changes in pulsational dynamics.[11,13,14] Multiple authors have pointed out that the Great Dimming coincided with the minima of both the 430 days and 5.8 year periods.[11,15,16] However, the observed decrease in temperature in the star could not be explained by pulsational dynamics alone.[12]

Nonlinear time series analysis on the light curve of Betelgeuse prior to the major dimming event suggested that a critical slowing down was observed in the light curve well before the actual dimming occurred. When a nonlinear dynamical system undergoes a change of state, it often does so suddenly and with no change in the mean response. However, prior to many such changes in state (called a critical transition), multiple time series quantifiers called early warning signals (EWS) are shown to increase.[17] The presence of critical slowing down in Betelgeuse indicated that the star was about to undergo a change of state in its dynamical properties. It was suggested that the dimming phenomenon was the change of state itself or occurred as a result of it.[14] This work suggested that the reasons behind the dimming could be explained by studying the light curve before the Great Dimming occurred.

In this paper we explore the dynamical properties of Betelgeuse in greater detail, by studying how they changed before, during and after the Great Dimming. We do this by analysing Wing three-filter TiO and V band photometry measured at

the Wasatonic Observatory[11,18] and V/Vis data from the American Association of Variable Star Observers (AAVSO).[19] We first gain further evidence for a dynamical change in Betelgeuse by studying the multiwavelength Wing data. We then study changes in the linear correlations between the wavelengths and study how they changed over the period leading up to the dimming. Finally we study how the quantifiers studied by George et al.[14] changed in the AAVSO light curve, in the period leading up to, during and after the Great Dimming.

2. Analysis

2.1. *Wing Three-filter and V-band Photometry*

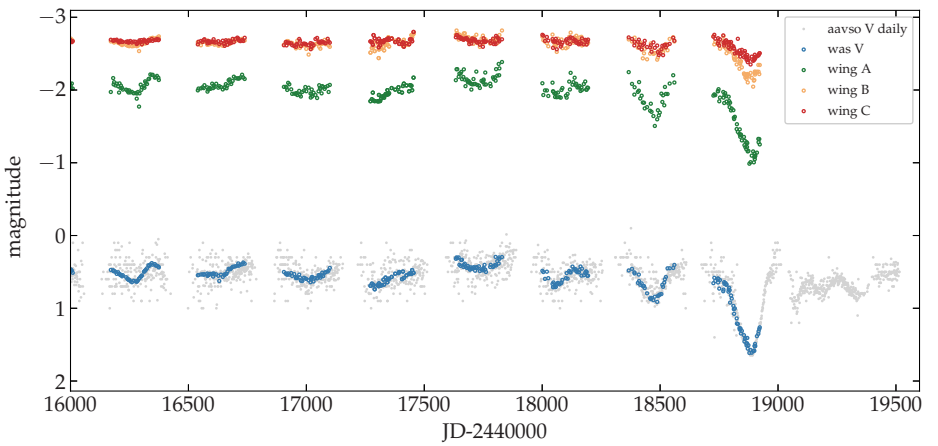

Fig. 1. Variation of intensity in Betelgeuse, as captured in Vis/V band AAVSO data (grey), V-band photometry from Wasatonic laboratory (blue), and Infrared Wing three-filter (A: green, B: orange, C: red) data.

Wing photometry consists of an eight band measurement of electromagnetic radiation from an astronomical source, initially developed for studying M supergiant stars.[20] Later, a simplified three-filter system was proposed that measures infrared magnitude, color and spectral type for a star.[21] In this study, photometric data (IR/near-IR) from three Wing filters,[21] and a wideband V filter collected by the Wasatonic observatory, are analyzed. The V-band filter is centered around 5550 Å. The Wing A filter is dominated by the TiO 7190 Å. The Wing B and C filters are continuum bands centered around 7500 Å and 10240 Å respectively. More information about the data may be found in Harper et al. (2020).[11]

We first calculate the cross-correlations (see figure 2 (a)), using Person Correlation Coefficient among data from different bands in a sliding window fashion with a window size = 300 points. The V-band and A band are already known to exhibit

strong correlation,[11] but we find that this correlation decreases prior to dimming. It is interesting that this trend starts much before the actual dimming episode, hinting towards a prolonged process. Moreover, we find this trend to be simultaneous in all pairs of data.

We then employ nonlinear time series analysis techniques to analyze the multivariate data. Building on dynamical systems theory, our techniques assume the existence of a state space representation for the data. Since dynamical features of the source are intimately related to the topological properties in state space, its quantification can yield valuable information.

One of these helpful properties is recurrence: the tendency of a system to visit the neighborhoods of previously occupied states. Recurrence is a prominent feature of deterministic dynamics and can be easily captured in terms of Euclidean distances among points on the attractor (trajectories) in state space.[22] When presented in matrix form, it is known as the Recurrence matrix (R). A 2-dimensional visual representation of R is known as the recurrence plot (RP). Statistical measures on RP, collectively known as the Recurrence Quantification Analysis (RQA), reveal subtle characteristics of the dynamics at play. Changes in some of these RQA measures may serve as EWS for a system close to a dynamical transition.[23] For the multivariate data, we make use of Recurrence Rate (RR) to study dynamical features of the Betelgeuse light curve.

We analyze recurrence properties of the data in the same sliding window fashion, keeping distance threshold constant at 0.1 for calculation of RP. We do this separately for each band, and present the results for RR (fraction of points in the recurrence matrix) in figure 2 (b). Again, we find an increasing trend in all wavelengths. Interestingly, the trend is most consistent for IR bands. Further, it corresponds well to the correlation indicated in figure 2 (a). This indicates that if there is a dynamical process at play, it may not be a peripheral phenomenon. Similar variation across bands hints at the possibility of change at the stellar scale, probably in the pulsation dynamics.

These results agree well with EWS observed in the AAVSO data,[19] reported previously.[14] However, the length of available data limits an extensive analysis, at this point in time.

2.2. *Beyond the Great Dimming*

In this section we present results on how the nonlinear parameters of the light curve changed after the Great Dimming, using V band data from the AAVSO.[19] In George et al. (2020),[14] we reported signatures of dynamical transitions in this data in the form of critical slowing down. We reported an increase in multiple EWS including the autocorrelation at lag 1 (ACF(1)), variance and recurrence based measures in the data leading up to the dimming. The increase in these quantifiers indicated

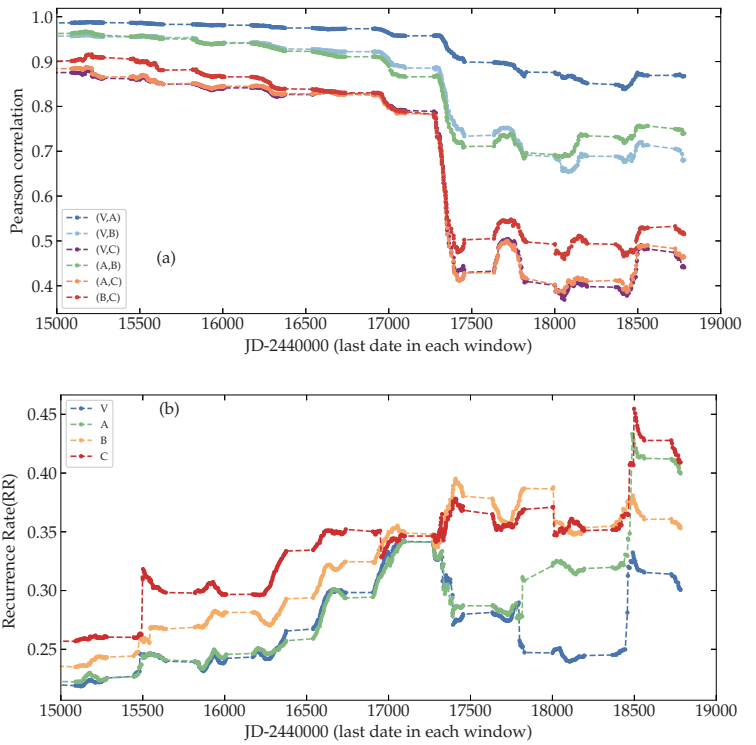

Fig. 2. (a) Cross-correlation between pairs of data from different bands calculated in a sliding window fashion upto (but not including) dimming. (b) Recurrence Rate (RR) obtained with fixed recurrence threshold = 0.1, for each band. Window size = 300.

that a critical transition was imminent. It was assumed that the Great Dimming occurred as a result of this critical transition. In the present paper we go beyond the Great Dimming and analyse how the EWS changed since.

2.2.1. *Autocorrelation and Variance*

To do this we initially bin the data from 1990 onwards into 10 day bins, and calculate the ACF(1) and variance in windows of size 300. This is presented in figure 3.1. Both the ACF(1) and Variance show an increase leading up to the dimming, a sharp rise when the Great Dimming occurred, and a slow reduction after the dimming ended. In figure 3.2 we select an area around the dimming, bin the data into 5 day bins and choose a window size of 40 points. The data again shows the same trends, with a rise leading up to the dimming, a sharp rise during the Great Dimming and a fall since. With the smaller window and bin size, the error on the quantifiers increases (changing approximately as $\frac{1}{\sqrt{n}}$).

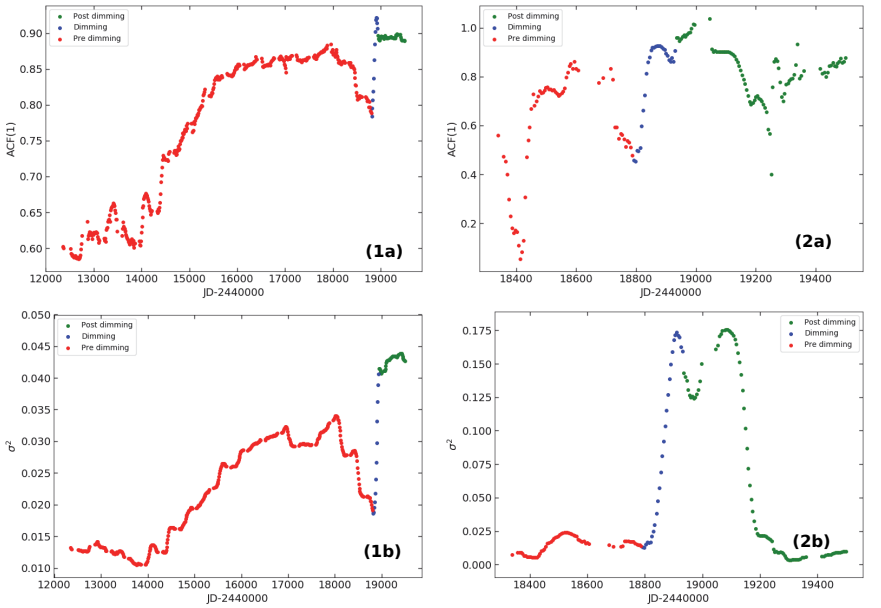

Fig. 3. Variation in the (a) Autocorrelation at lag 1 and (b) Variance calculated from the light curve of Betelgeuse upto the dimming (red), during the dimming (blue) and post dimming (green). The left panels (figures 1a and 1b) show the variation from 1990 onwards using a window size of 300 points on data binned every 10 days. The right panels zoom into a region around the dimming, with data binned every 5 days with a window size of 40.

2.2.2. *Recurrence Measures*

We then analyze AAVSO data in terms of recurrence measures as well. For this, we fix the recurrence rate (RR) as 0.1, and calculate Determinism (DET) and Laminarity (LAM) in the same sliding window fashion. We find a consistent rise in these measures prior to dimming, followed by a sudden dip and subsequent rise (see figure 4 (a) and (b)). We also present typical recurrence plots for two windows near dimming episode (one prior and one including dimming) in figure 4 (c) and (d) respectively as a visual aid. Clearly, the sudden drop in brightness affects the structure of the RP, and the recurrence measures reflect it. However, it is interesting to see the rise prior to dimming, possibly caused by dynamical factors (details discussed in George et al.[14]). The trend in post dimming behaviour seems in agreement which could be verified with future observations in the coming years.

3. Discussion

We presented the nonlinear analysis on two datasets measuring the brightness of Betelgeuse before, during and after the Great Dimming of 2019-20. We conducted a multivariate time series analysis of the data from Wing-IR photometry and the

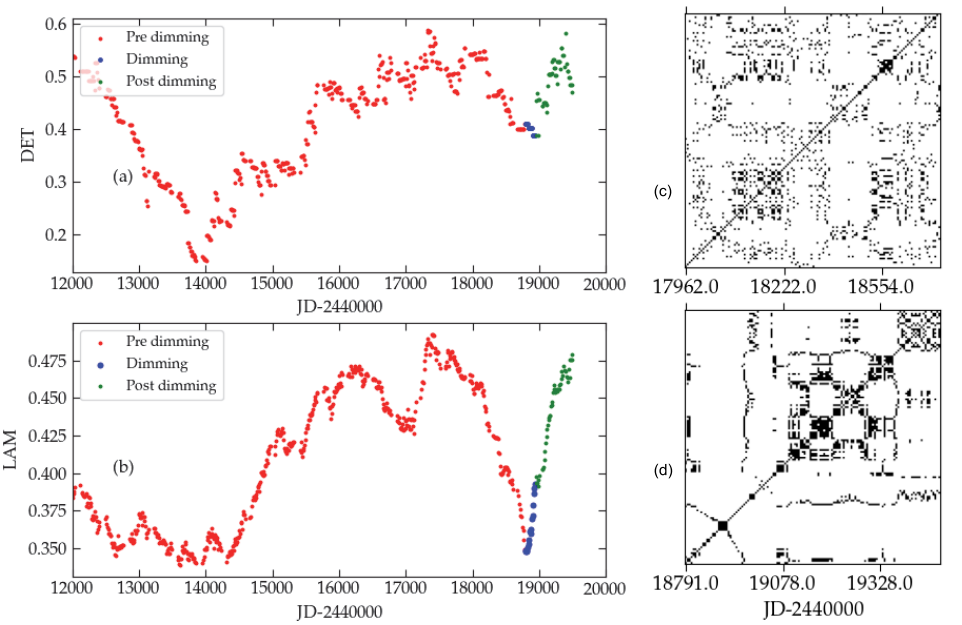

Fig. 4. Recurrence measures (a) Determinism (DET) and (b) Laminarity (LAM) calculated from the light curve of Betelgeuse upto the dimming (red), during (blue), and post dimming (green). The left panels (figures a and b) show the variation from 1990 onwards using a window size of 300 points on data binned every 10 days. The right panels (figures c and d) show typical recurrence plots for prior and during dimming respectively. The recurrence rate was fixed at 0.1.

V band photometry from Wasatonic laboratory. We show that prior to the dimming, the cross correlations and individual recurrence measures vary considerably. Our results suggest that a change in the dynamics of Betelgeuse commenced in advance of the Great Dimming of 2019-20. We also analyse early warning signals in AAVSO light curve for the period including and after the Great Dimming. While not conclusive, we see evidence that the values of the early warning signals have reduced since the Great Dimming.

Our results make a strong case that the dynamics of Betelgeuse underwent significant changes leading up to the Great Dimming. Variable stars are known to undergo changes in their nonlinear properties as they evolve.[24–26] In this study we observe that the recurrence properties, cross correlations and early warning signals change prior to the Great Dimming. In addition, Betelgeuse is known to exhibit multiple frequencies in its light curve, including a short period, thought to be driven by the κ mechanism, a long period thought to be convection driven[27] and a recently detected overtone of the short period.[11,28] It is possible that the pulsational dynamics of Betelgeuse, including the birth of new periods may have preceded the Great Dimming, and these need to be examined in detail.

Taken together with the study on the light curve of Betelgeuse by George et al. (2020),[14] our results seem to indicate that the Great Dimming was not an isolated incident, and to understand the reasons for the dimming, we must consider changes in the dynamics before it.

Acknowledgments

We acknowledge Dr. Graham Harper for useful discussions, and Richard Wasatonic and Prof. Edward Guinan for the multi wavelength data used in this study. We acknowledge with thanks the variable star observations from the AAVSO International Database contributed by observers worldwide and used in this research. SVG acknowledges financial support from the European Research Council (ERC) under the European Union's Horizon 2020 research and innovative programme (ERC-CoG-2015; No 681466 awarded to M. Wichers). SK acknowledges financial support from the Council of Scientific and Industrial Research (CSIR), India.

The curious case of Betelgeuse

Jacco Th. van Loon

Betelgeuse is the nearest red supergiant, one of the brightest stars in our sky, and statistically speaking it would be expected to be "typical". Yet it exhibits many features that seem "curious", to say the least. For instance it has a high proper motion. It rotates fast. It has little dust. It dimmed unexpectedly. Is any of these, and other, phenomena atypical, and taken together does it make Betelgeuse atypical? This is important to know, because we need to know whether Betelgeuse might be a prototype of red supergiants in general, or certain subclasses of red supergiants, since we can study it in such great detail. It is also important to know as it may be a link to understanding other, apparently atypical cases such as supernova 1987A, and maybe even such exotica as Thorne-Żytkov objects. Studying this question in itself helps us understand how we deal with rarity and coincidence in understanding the Universe we live in.

Keywords: Red supergiants – stellar variability – dust formation – supernova progenitors – Philosophy of Science – Betelgeuse.

1. Prologue

Not far in the sky from the most famous supernova remnant, the Crab Nebula, the most famous red supergiant, Betelgeuse, has been a familiar sight for peoples in either hemisphere. Distinctively orange, and one of the brightest lights on the nightly celestial firmament, its prominent position in the corner of arguably the most iconic constellation, Orion, Betelgeuse commands our attention and this in itself makes it special. This perspective aims to challenge the uniqueness and surprising behaviour of many a favourite star, and what it tells us about us. It could be seen as a more philosophical sequel to the Paris 2012 workshop on Betelgeuse.[1]

2. Is Betelgeuse typical?

It's got to be, right? Surely, as the nearest example of a red supergiant, Betelgeuse must be ordinary? This is because the chances are favourable for a draw of one from among many to be drawn from the most common.

While this may often be true, and hence unremarkable and thus unnoticed, it is not always the case, as is expected when considering many draws from samples that do include rare examples. (The basis for many false associations, let alone causal relationships.) For instance, the first supernova witnessed by naked eye for three centuries, and the best studied, supernova 1987A wasn't! It had been expected to

have been a star like Betelgeuse to have exploded, and yet it was all but. (Though they may have much more in common than at first sight.[1])

We are not placed in a typical red supergiant environment. While within a Bubble created by multiple supernovæ, we are not currently situated in a spiral arm. So perhaps Betelgeuse is typical for this particular environment, but not necessarily for red supergiants that are largely found in the denser, more actively star-forming regions of a spiral galaxy such as the spectacular H II regions in the prominent spiral arms several times more distant, or the even more distant massive clusters near the Galactic Centre.

But all things considered, Betelgeuse does not stand out in either luminosity, temperature, mass-loss rate or dust content – in fact it looks like a fairly commonly identified SN II-P progenitor![2] (But this may partly be a selection bias of the progenitor identification strategies.)

3. Is Betelgeuse atypical?

Just like most people look similar – four limbs, a head with a pair of eyes and ears and a nose upfront – when inspected more closely individual traits set us apart. This doesn't make each specimen a species, and in the end, we have much more in common than differentiates us, both in terms of the way we look and the way we behave.

Among Betelgeuse's perplexities count its location at some distance from sites of recent star formation, its large space motion, and a picture-perfect bow shock.[3] Upon close inspection, it spins at a baffling rate[4,5] and also is super-nitrogenous.[6]

And then came the 'Great Dimming'.[7] (Which may have nothing or all to do with the above.) A drop in brightness by half relegated Betelgeuse to the realm of much more inconspicuous stars, but sent alarm bells ringing with fears – or excitement – for its imminent luminous demise.

But none have been scrutinised as much as Betelgeuse. Brief late phases of underrepresented stars at birth, red supergiants themselves are rare, so few are seen up as close as Betelgeuse. It is not how well we know Betelgeuse, but how poorly we know the other red supergiants that defines its curiousness.

4. Our one-sided view of Betelgeuse

Because of the attention it has recently received, we shall first unpick how rare is Betelgeuse's Great Dimming, before we return to its full portfolio of properties.

By our very own nature as observers and thinking minds, and our position in the Universe, we suffer from anthropocentric bias: just because *we* didn't see it before, or elsewhere, doesn't make it rare per se. The 20$^{\text{th}}$-century artist Pablo Picasso exposed this imperfect picture by recovering what is hidden from view in a form referred to as "cubism". But how do we do that in reality? Do we know it? Do we infer it? Or do we ignore it? If you look out into a field and see what looks like a

black lamb, what do you conclude? That:

- lambs are black?
- lambs exist that are black?
- lambs exist of which at least one side is black?
- apparitions exist that look like lambs of which at least one side is black?

Despite well-known examples of non-isotropy in astronomy (cf. exoplanet transits, γ-ray bursts, pulsars) it is too often overlooked.

Betelgeuse forms dust clouds episodically, as convection cells cause dark spots[8] that induce cooler circumstellar conditions where dust can form,[9] likely in an already cooler parcel of lifted gas.[10] In the case of Betelgeuse this is exacerbated because Betelgeuse is on the cusp between a warm chromosphere and dusty wind.[11] Counting the number of dust clouds and considering their projected distances from Betelgeuse, a dust cloud forms about once every five years!

Imagine Betelgeuse were cubic and we only faced one side at a time (compare a standard die), then we'd only see one in every six events randomly happening on one of its sides. (In reality the polar and equatorial regions may display different behaviour especially in the case of a rapidly spinning Betelgeuse.) This means we *may* have had a Great Dimming *on our side* once every few decades (cf. the visual lightcurve[12]), but we *certainly* missed Great Dimmings happening *on another side*!

It is tempting to expect a dust cloud to form at every minimum in the $\sim$ 2000 day cycle. But that depends on whether this periodicity represents radial pulsation (in which case it is true) or convectional modulation – in which case the five-yearly cloud would always be in front, though other clouds would be forming more frequently throughout, above cool convection cells not seen by us, hence being in tension with observational evidence. It is more likely that a dust cloud forms at a pulsational minimum but only above a cool convection cell (the latter causing the $\sim$ 400-day cycle, but again that's our biased perspective, there could be a cool convection cell *somewhere* on the surface at all times). In fact, forming at some height above the surface, such dust cloud is less likely to be seen directly in front of the star than the convection cell is – at one stellar radius above the surface this chance is already diminished by a factor four. (Note that even the cloud purported to have caused the Great Dimming did not cover the entire face of Betelgeuse.[7]) The Great Dimming might have been our treat, but bread and butter for Betelgeuse.

Previous dimmings have been disputed, but it is not outrageous if of a few expected *chance* occurrences (as opposed to *predicted* events) just one has materialised. A century is not a very long time span in the life of a star, even that of a red supergiant (one pro mille!), and Betelgeuse may have exhibited many more dimmings, and may exhibit many more to come. Our Sun has arguably been more dramatic, as we know it so well: the sunspot cycle is a fairly regular rythm of activity, but we are still astounded by the Maunder Minimum of the late-17$^{\text{th}}$ and early-18$^{\text{th}}$ centuries – what if the telescope had only been invented a century later? (We would never have known.)

5. How common are anomalies?

If Betelgeuse ought to be common for being the nearest red supergiant, then so should be Antares for being only the second-nearest red supergiant. But as we argued, this is not a given. It would be much less likely, though, if both Betelgeuse *and* Antares were special. This then begs the question: is Betelgeuse different from Antares?

Antares has similar luminosity, temperature, convection,[13] mass loss, (low) dust content and lightcurve (with similar dimmings). Like Betelgeuse, it produces discrete dust clouds.[14,15] But Antares is a *slow* rotator and is accompanied by a hot star (on a sufficiently wide orbit not to be directly affected by it). How different does that make them?

Imagine stars are characterised by five features, that each have a 1:10 chance of being anomalous (imagine a ten-sided die). Then 1:2 stars are expected to be anomalous. Every other star. So a star is just as likely to be common as it is to be anomalous, despite the majority of stars to be common in any given feature. It should not come as a surprise if both Betelgeuse and Antares had some properties that are rare among the general population of red supergiants. This is what makes individual people distinctive.

Imagine another scenario, where a penguin among other penguins in a colony is distinguished by:

- the colour of its coat: blue (as opposed to brown).
- the texture of its coat: smooth (as opposed to fluffy).
- the colour of its cheeks: yellow.
- the colour of the underbill: orange.

Does that make this individual penguin anomalous in four ways? Most definitely not! It is anomalous in just one way: being an adult (surrounded by infants)!

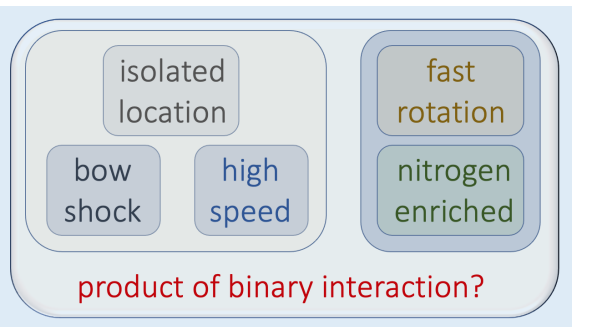

Fig. 1. Betelgeuse has various characteristics which have been treated as peculiarities. Irrespective of whether these are indeed oddities at all, they can be reduced to fewer characteristics – possibly just one – for which there may well be a totally reasonable – if not banal – explanation.

Returning to the curious case of Betelgeuse, its isolated location, high speed and bow shock are all related, and so may be its fast rotation and nitrogen enrichment – both can be reconciled into one: binary interaction (Fig. 1). And a common one at that: 10–40 per cent of massive stars will be affected by a companion.[16–18]

Then which is more special: Betelgeuse or Antares? Neither – both cases are expected equally: the result of binary interaction (Betelgeuse) and multiple but unaffected (Antares). The nearby Universe thus seems to be living up to expectations remarkably well!

6. How to find out how common is Betelgeuse?

Moving onwards, if we want to find out what red supergiants typically look like, how they generally evolve, and how and why some may deviate from the norm, we will not succeed in this by studying Betelgeuse harder and longer, but by statistical studies of samples of other red supergiants, such as:

- lightcurve studies based on sparse and/or time-limited data but for large samples in nearby galaxies ('Great Dimmings' may be seen in other galaxies, too[19]).
- nitrogen abundance measurements and their link with rotation.
- radial velocity monitoring and spectral energy distributions, to determine binary fractions.
- three-dimensional space motion studies in conjunction with rejuvenation scenarios, to determine past binary interactions.
- interferometric size measurements in relation to the location on the Hertzsprung–Russell Diagram, and mass (loss) measurements from seismology.

Fig. 2. What draws your eye? The white canvas that occupies most of what you're looking at? Or the black dot offset from the centre, which only covers a tiny fraction of your view? We are drawn to the exceptional, not the norm.

7. Epilogue

The take-away message from this discussion is that when making inferences we need to account for biases. We tend to look for the distinctive, not the common. For instance, when we look at a white panel with a black dot (Fig. 2) our attention is drawn to the dot even though it occupies much less space than the rest of the canvass. Just as we occupy ourselves with the few per cent of baryonic Universe, preferentially in its condensed forms, leaving the vastness of space largely neglected. If we saw less of the canvass, we might have missed the black dot altogether, but if we saw more we might find out black dots to be rather common!

Acknowledgements

I'd like to thank Costantino Sigismondi for organising the Betelgeuse session at the 16^{th} Marcel Grossmann meeting and for inviting me to speak.

Variable stars observed from city sites: The 2500 AAVSO-SGQ database

Costantino Sigismondi
ICRA, Sapienza University of Rome,
Rome, Italy
E-mail: sigismondi@icra.it
http://www.icra.it/solar

Paolo Ochner
Padova University and Asiago Astrophysical Observatory, Italy

The observations of Betelgeuse since Christmas 2011 were started either to study the star and to contribute to observational astronomy from urban contexts, with high level of light pollution, using the naked eye. Since then 811 observations to November 9, 2021 have been made and communicated to the AAVSO international database. Antares and also other interesting long-period variable stars like VY CMa, RS Oph (recurrent nova), V766 Cen and several novae and SN2014J are part of the 2.5 K database of visual observations, obtained with the Argelander method applied to naked eye or telescopic observations. It is an invitation for the young generations, to contribute to these studies with careful and feasible observations, which require a reduction for airmass extinction of the variable star and of the comparison stars, when they are not on the same narrow field of view. The possibility to deduce the airmass by reading the notes (containing the location of the observation) of all the AAVSO-SGQ catalogue is finally presented as a point of force of my observations.

Keywords: Mira, Betelgeuse; Eta Carinae; VY Canis Majoris; RS Ophiuchi, Antares; V766 Cen, Novae, SN2014J

1. Theory and observations in history of astronomy

I observe variable stars since 1997, I have started with Mira. The "candidacy" of Mira Ceti as Betlehem Star because it is close to the position of the Jupiter-Saturn triple conjunction of 6-7 b.C. was conceived by me at the Pontifical University of Lateran and the study was continued in Yale (2001-2004) with Dorrit Hoffleit. Maxima correlation function ruled out Mira for having two consecutive bright maxima, but this property was confirmed in the "oldest" Myra-type: R Leonis, R Hydrae and χ Cygni, from their almost four-century-long lightcurves. To a bright maximum normally a dim one follows, as the correlation function of their consecutive maxima shows. These studies were supported by historical and personal visual observations. Since 2011 I observe two first magnitude variable stars, with airmass correction to reach 0.01 magnitudes accuracy with naked eye.

AAVSO observer Sebastian Otero first claimed this accuracy, as for his first data on Nova Centauri 2013, observed also by me from Porto Alegre and Rio de Janeiro.

Betelgeuse's 811 observations in 10 years, include the deep minimum of 2020.

My SGQ contributions to AAVSO-database, paralleled with Betelgeuse's V-band measurements, help to define the "personal equations" present in all $25M$ visual observations before CCD era (1911-on) going back to 1893 for Betelgeuse.

2. Light curves completeness

The temporal extension of lightcurves is crucial to understand the stellar behaviour. With respect to Betelgeuse, more complicate cases are Antares and Aldebaran, less variable and with distant comparison stars. The Southern hypergiants VY CMa, low in the roman horizon, V766 Cen and Eta Carinae from South America in 1999, 2003 and 2013-2014 have been also monitored with binoculars or small telescopes. Delta Scorpii (Be binary star, whose system was at periastron in 2011) has also been studied from Rio de Janeiro, since 2011. Concluding: my 2.5K direct visual observations in nearly 25 years are data and experience useful to understand and simulate the accuracy of the World largest visual observations database for variable stars, the AAVSO one.

3. Betelgeuse among the long-period variable star

Betelgeuse is indeed the brightest variable star, but not the bigger one. Roughly the pulsational periods are proportional to the mass of the star through the relation that we found in the harmonic oscillators between the elastic force and the frequency and the mass: $K \times x = F = m\omega^2 \times x$.

Then $\omega = \sqrt{K/m}$. This physical assumption is very simple, and basic; it not fulfills all observational details nowadays available, but is a good starting point to interpret the difference of 9 years of observations of Betelgeuse with the ones of Antares.

The oscillation of Betelgeuse is evident and its main period is visible, while Antares shows either an oscillation and a rising trend.

Eta Carinae in 15 years (from 1999 to 2014) also showed a rising trend, while V766 Cen and VY CMa have been measured only for a short period, below one month, and other observers or future observations will allow to detect a trend.

4. Betelgeuse and Antares: Airmass correction and trends

From 2011 to 2021 Antares in the AAVSO database has been observed 619 times by 13 persons (only 3 with more than 10 observations). In the same time interval Betelgeuse has been observed nearly 14000 times by 360 observers. Not necessarily more observations are better, because of the "personal equations", or the systematic effect of each observer can experience for the Purkinje effect (physiological and slightly different from one individual to another), or the airmass extinction not applied when the comparison stars are far apart from the star.

The data of all the observers fill completely a full magnitude range for these reasons.

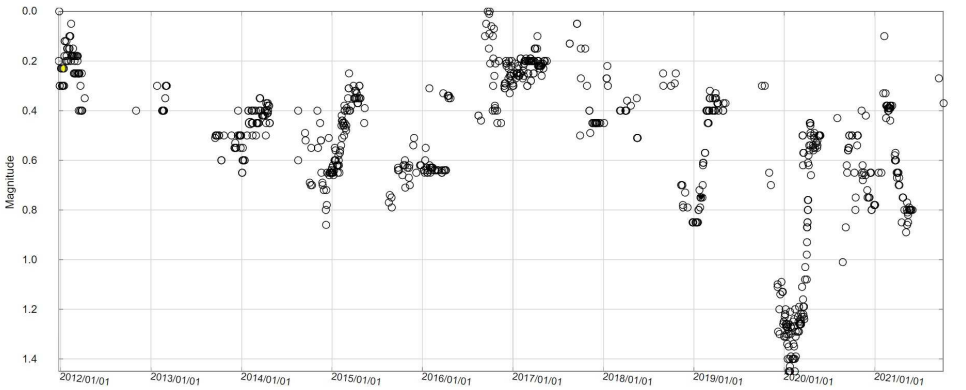

Fig. 1. The observations of Betelgeuse from 2011 to 2021 by Costantino Sigismondi, SGQ AAVSO observer.

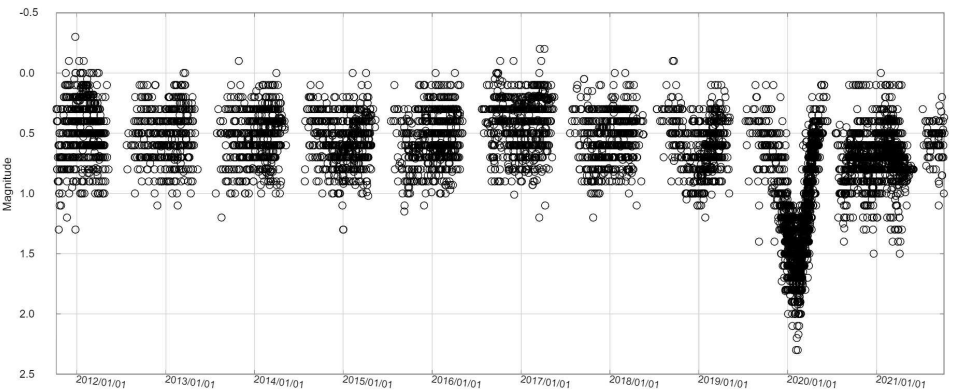

Fig. 2. All visual observations of Betelgeuse from 2011 to 2021 by the AAVSO observers: the oscillations are less evident, only the one during the deep minimum is clear. This was because Betelgeuse was at the meridian during this phase, around midnight, and its altitude was nearly constant night after night. The magnitude of the minimum from all data has a wide uncertainty. Only few visual data, still the majority for Betelgeuse, are corrected for the airmass: this is the cause of such uncertainties. The yearly gap due to solar conjunction is the most clear feature.

In the case of Betelgeuse I suppose that the airmass extinction is not applied by the majority of the observers, so I select only the obervers that I know personally as applying that correction.

Antares is a more Southern star (less observers in the Southern hemisphere), and even more separated by the comparison stars, then its measurements are more complicate. The amplitude of its variability is smaller than Betelgeuse's. These difficulties may explain the rather low number of observations available: 4% with respect to Betelgeuse. The oscillation I have detected are not clearly distinct from a yearly period, which seems related to the altitude above the horizon of the star

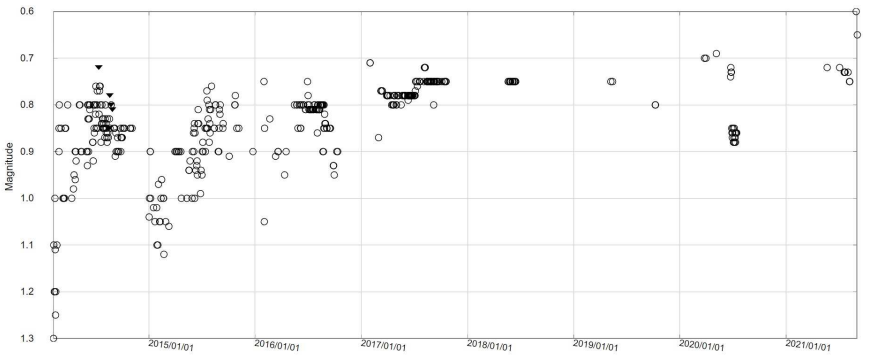

Fig. 3. The observations of Antares from 2014 to 2021 by Costantino Sigismondi, SGQ AAVSO observer.

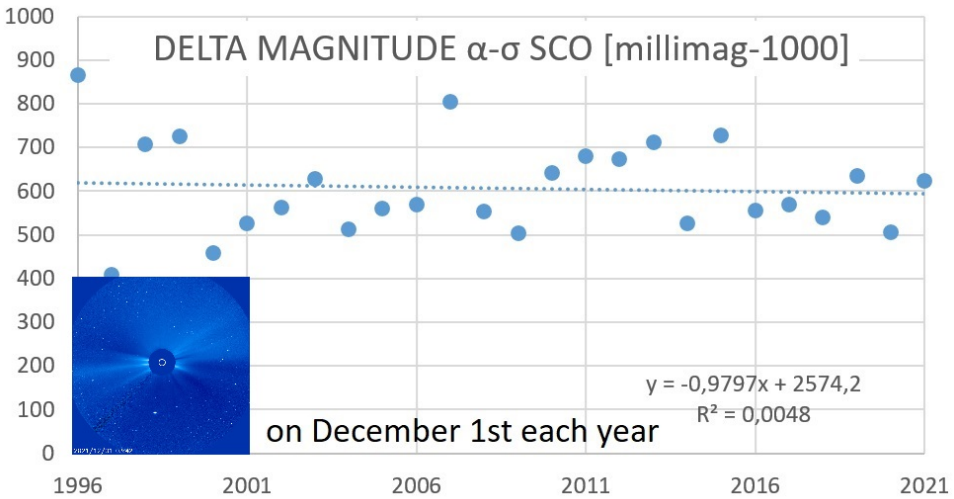

Fig. 4. The observations of Antares from 1996 to 2021 obtained by LASCO C3 Coronograph with the differential photometry made with σ Scorpii. The icon shows the image of Dec 1st, 2021.

observed at a given evening hour, and not to the star itself. The trend of the increase of the luminosity is more evident from these data.

As Betelgeuse, Antares presents rather rapid changes of luminosity during its period of visibility. No trend over the 2.5 decades can be guessed by either the visual data and the sampling each 1st of December, made with the SOHO LASCO C3 Coronograph, which includes for some days a year Antares in its field of view. That Coronograph could show stars of 5th magnitude under low activity of the solar corona. Antares is nearly saturated with this instrument, because it shows a lateral photons' spilling.

5. Recovering airmass on the AAVSO-SGQ observations' catalogue

The airmass of all variable stars can be calculated on AAVSO-SGQ catalogue by selecting SGQ as observer, in searching Alf Ori observations (and all the other variable stars observed).

The location of the observation is always reported in the notes, and the time is required by the application form. So the data for recomputing the airmass are made available.

Fig. 5. Example on V766 Centauri of the information contained in the notes: RJ is the city, Rio de Janeiro, and the address allows to have from google maps the geographical coordinates of the observation. From the time the altitude h° in the sky of the star is obtained, yielding the airmass with the cosecant law $1/\sin(h°)$

6. Conclusions and Perspectives: The quality of SGQ observations

The luminosity of Betelgeuse allowed to study that star in each condition from urban sites, namely for my observations Paris, Rome, Rio de Janeiro, Warsaw, without very dark skies neither without the possibility to be well screened from the light directed toward my eyes. The oscillations at the main period of 1.2 years are clearly detected.

More complicate has been the study of **Antares** which is farther from its comparison stars than Betelgeuse, and which is closer to the horizon for all the European cities. The oscillation of Antares is ranging from 1.16 to 0.88 according to the General Catalgue of Variable Stars 5.1, but my observations of the Summer 2021 found it around the magnitude 0.70 ± 0.05, at its maximum since 7 years. For Antares the comparison with Saturn was useful in the last years, and the planet has also a "light-curve" due to the geometrical change of the rings' plane. The small oscillations of Antares are not clearly detected for the aforementioned difficulties: at the horizon there are more obstacles and the atmospheric extinction is not linear with the cosecant of the altitude $1/sin(h°)$. In the General Catalogue of Variable Stars 5.1 the is no value for the oscillating period of Antares. It is classified as LC variable, and according to wikipedia it means: *A slow irregular variable (ascribed the GCVS types L, LB and LC) is a variable star that exhibit no or very poorly defined*

periodicity in their slowly changing light emissions. These stars have often been little-studied, and once more is learnt about them, they are reclassified into other categories such as semiregular variables. A long period study on the variability of Antares has conducted by me following a 2014 study on Delta Scorpii, with the SOHO C3 coronograph. The next datum from SOHO C3 will be available 15 days after the closure of these proceedings, on December 1st 2021. This measure will be interesting since in the summer 2021 Antares has shown the brightest luminosity of the last 7 years. The two datasets of **Eta Carinae** in 1999 and in 2013-4 allow to see its slow rising. The other hypergiant **V766 Cen** and **VY CMa** have been observed for a short time slot, and will be compared with future observations. For them the differential magnitude has been estimated with stars in the same or near the telescopic field of view, being them not visible to the naked eye. Actually Eta Carinae could be visible with the naked eye, but not in the city lights. To observe it from Rio de Janeiro (Copacabana seaside with a strong illumination in 2003 and Observatorio Nacional in 2013) I had to use a small telescope. The recurrent nova **RS Oph** (2021, 24 observations along the month 8 August-12 September down to magnitude 9 with a 76 mm telescope, fig. 5), other Novae in Sagittarius from 2015 to 2018 and the SN 2014J are part of this personal database of 2564 high quality visual observations to date (9 November 2021), available to the science community.

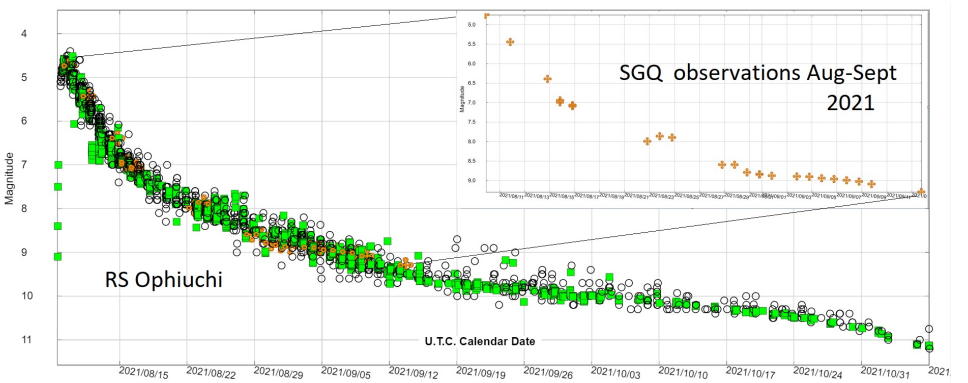

Fig. 6. The AAVSO light curve of RS Oph with the SGQ contributions evidenced in orange. They are compared with the V-band observations, and they are in very good agreement.

Tiziana Pompa
Liceo Galilei, Pescara, Italy

Betelgeuse is the brightest variable star in the sky, with a pulsational main period of 14 months and typical magnitude variation of 0.5 magnitudes. In 2020 its deep dimming was of one whole magnitude, particularly evident to each attentive observer. The technique of airmass correction to detect the stellar signal from the atmospheric extinction treats the naked eye observations as the digital astronomical observations. Harlow Shapley said in 1930s "theories come and go, while a good observation stands forever" and he spoke about naked eye observations, nowadays they are less considered in science mainly because of philosophical reasons concerning the subjectivity of knowledge and the deceit of the senses, while the knowledge of the eye physiology and of data reduction could recover the correct relationship between the human being and the Universe.

Keywords: Betelgeuse; Red giant; Variable stars, Atmospheric Extinction, Quadrant.

1. General Overview on observing Betelgeuse

According to Dorrit Hoffleit (1907-2007) director of the Maria Mitchell Observatory and astronomer at Yale University, Mira is the educational star. But it requires the use of a telescope at its minimum, and a binocular for its maximum phase, to spot it in city lights. Betelgeuse is a semiregular variable star of first magnitude, in the most famous constellation in the sky, visible from both hemispheres because it is on the celestial equator. It is visible (to the naked eye) for nine months a year. Its magnitude estimate, according to the Argelander method, requires other first magnitude stars, separated by several degrees, at rather different airmasses.

Procyon, Aldebaran, Pollux, Castor as well as γ Geminorum, Regulus, Denebola, Mars and even Mercury have been used as comparison stars, and their airmass corrections included.

Since January 2019 we steered a project in schools to observe and measure the light curve of Betelgeuse. We observed Betelgeuse and its comparison stars with a special colored quadrant where the angular height in sight corresponds to the airmass exctinction with respect to the zenit. The schools were the Lyceum Morgagni and Ferraris in Rome and Ostia and the Lyceum Galilei in Pescara.

Fig. 1. The observations made during the meeting of 2020 during the Great Dimming.

The great dimming of Betelgeuse was then observed and measured to the nearest 0.01 magnitude at naked eye (fig. 1).

These observations have been sent to AAVSO, as contributes of students to citizen science. Similar operations have been realized with the students of the Astrophysics Laboratory, Sapienza University of Rome. Summer vactions' homework are "offered" by Antares, a first magnitude stars greatly separated by its more suitable comparison stars. Recently Saturn worked as reference, but a planet is not a constant standard candle. The introduction to photometry, colorimetry and spectrometry with these naked-eye cases is complete and historically meaningful.

2. Colorimetry: From the spectrum to the Newton's disk

The color of the stars is something lost in city environment, because lost is the visibility of the sky in general, owing to the artificial light directed toward our eyes and toward the sky. Betelgeuse is clearly a red star, and it can be noticed by comparing it with Procyon or Rigel, normally used as comparison stars for magnitude's estimates, or Sirius, that are rather close to Betelgeuse.

The Newton's disk for solar spectrum has been replicated for Betelgeuse with red-yellowish tonalities.

The connection between the color of the star and the its temperature can be done by noticing the percentage of color of a given wavelength, as represented in the Newton's disk. Basically the Wien's law is represented with the apple pie diagram: the largest sector corresponds to the wavelength of the maximum intensity in the spectrum.

3. Betelgeuse the brightest long-period variable star

Among the variable stars Betelgeuse is indeed the brightest, and the most simple one to be detected thanks to its location in Orion, near the celestial equator. This

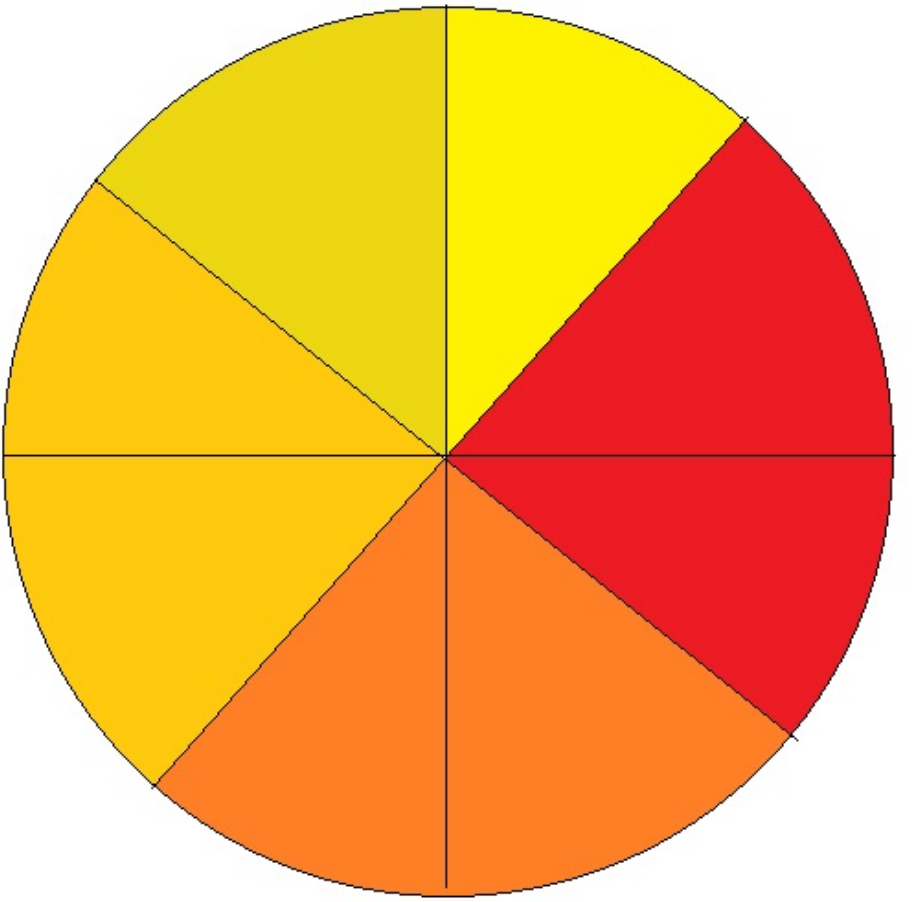

Fig. 2. Colorimetry: the Newton's disk of Betelgeuse as realized by 14 years old students in 2020.

position makes Betelgeuse popular either from the Northern and the Southern hemispheres. The period of main oscillation is 1 year and two months, and the secondary modulating period is almost six years. In a reasonable space of time achievable by a school class program, the star can be followed from a maximum through the following minimum to the next one maximum, i.e. a complete oscillation. This allows the students to familiarize with the oscillating nature of such phenomenon, and primarily with the fact that among the "fixed" stars something changes and within a factor of two in intensity (2.512 times for a whole magnitude gap from minimum to maximum) even if the star is a supergiant as Betelgeuse is.

4. The quadrant for the airmass correction

Hanging a weight on the top right corner of the quadrant in figure 3, the thread shows the magnitude's correction and the corresponding angular altitude of the

star. The brighter stars used as comparison stars with the Argelander's method are reported near the bottom left corner: Aldebaran, Procyon, Rigel, Spica, Regulus and Deneb. There are not Pollux and Castor of Gemini, neither Bellatrix in Orion, stars dimmer than 1.2 magnitude, which in January 2019, when the quadrant was designed, were out of the last four-decades range of variation of Betelgeuse.

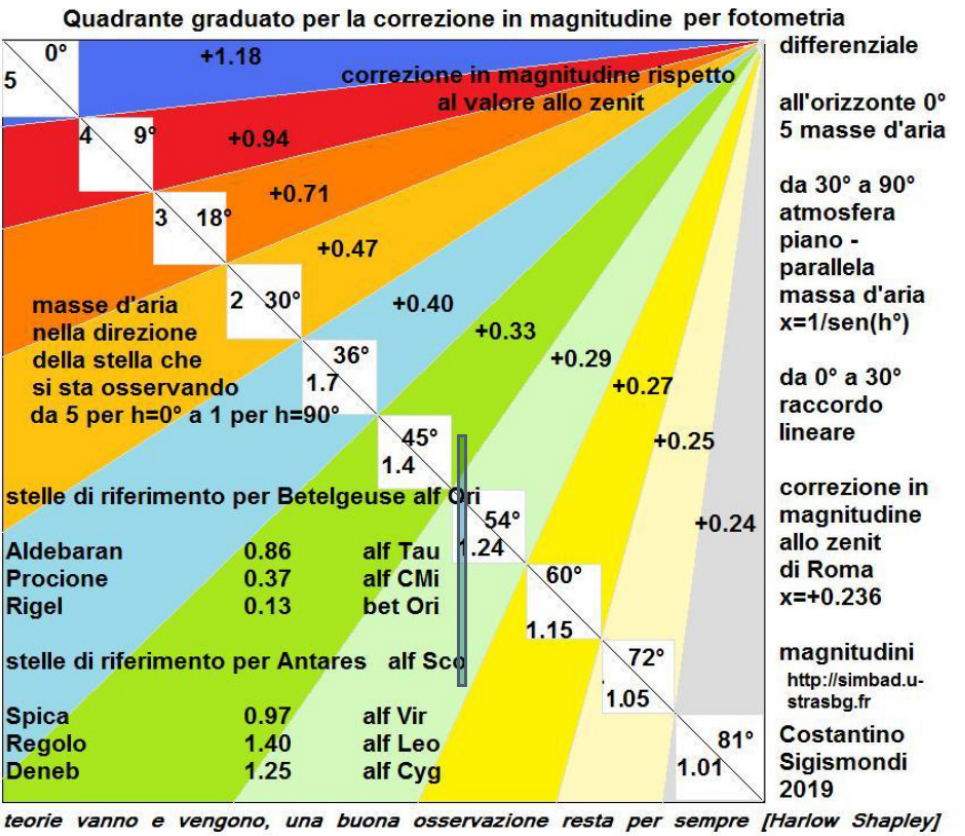

Fig. 3. The quadrant prepared for the observations of Betelgeuse for the students of the Morgagni Lyceum in Rome and the Galilei Lyceum in Pescara.

5. Data reduction

It is not obvious for a young student that an astronomical observation, or an experiment in general, require a data treatment, to be presented or to be analyzed to obtain science results. In particular an observation with naked eyes seems something really far from the data analysis concept. While a light-curve shows the intrinsic "behaviour" of a star, and it is exactly what we want to observe and measure, a single observation made with the naked eye seems a static datum. The difference in altitude of the stars determines a different atmospheric extinction acting on them,

Fig. 4. The airmass table for Rome with $\Delta Mag = 0.236/sin(h)$.

Fig. 5. The quadrants realized for the special event of the Betelgeuse Deep Minimum Meeting of January, 17th 2020.

and this computation has to be done for each of the observed stars: Betelgeuse and the two bracketing comparison stars (Aldebaran and Procyon, usually). This operation generate a system of two first order equations in the incognita *magnitude* of the variable star. The solution of such system is a range of magnitudes for the variable star, hopefully as narrow as 0.05 or 0.02 magnitudes. The data reduction can be made also by using Stellarium 0.20.2, ad higher versions, where an extinction's model is implemented. With respect to Betelgeuse Stellarium airmass fails below 10° and our quadrant is more reliable.

6. Conclusions and Perspectives

Betelgeuse is a good "student star" or the "educational star" following Dorrit Hoffleit. She was applying such definition for Mira Ceti (from 2nd magnitude to 9th) but the students were College students with an astronomical telescope available. Betelgeuse requires attention indeed, but it is visible always to the naked eye. It is visible also from the light-polluted cities, and the observations can be done from their home, as homework, rather easily from September-November before sunrise to April-May after sunset, and nearly all night long in between. The possibility to participate to AAVSO observational campaigns, with a real citizen science contribution can stimulate the most interested students to pursue the way of a scientific career in astronomy.

The meridian line of the Vatican obelisk to study the stellar aberration

Costantino Sigismondi

Rome, Italy
E-mail: sigismondi@icra.it
www.icra.it/solar

Lorenzo Ricciardi
University of Rome 3,
Rome, Italy

The first evidence of the stellar aberration come out from telescopic meridian observations, including daytime ones. The distance in ecliptic longitude between the star and the Sun has to change from 180° to 90° to have the maximum effect in the delay of the transit, with respect to a constant sidereal day of 23h 56m 04.09s. We present the measurements of meridian transits of Antares and Ras Alhague during the Summer 2021, at the meridian line of St. Peter's square, whose gnomon is the Vatican obelisk. The possibility to observe such transits in daylight has been also verified with Antares (21 August, 2021) and Venus (October 2021). The geometry of the instrument and its configuration is ideal to introduce students to the observations of this special relativistic effect, from an experimental point of view. The transits observed from the same position, the Scorpio zodiacal disk, from October 16 to November 11, 2021 permitted to scan the axis of the obelisk and the one of the uppermost cross, finding an offaxis of (16±3) mm West for the upper pyramid and a further deviation of (5 ± 3) mm West of the cross.

Keywords: Vatican obelisk; Meridian line; Stellar Aberration; Ecliptic longitude; Sidereal day.

1. The Vatican obelisk and the meridian line of St. Peter's square

The Egyptian obelisk was carried in Rome by Emperor Caligola and set on the Vatican Circus. It was the only one which survived along the middle ages, considered the witness of the martyrdom of the apostle St. Peter. Pope Sixtus V and the architect Domenico Fontana moved it in front of the Basilica of St. Peter in 1586 with the special design to emulate and surpass the Augustus' obelisk mentioned by Plinius the Elder in his Naturalis Historia. The Dominican astronomer Egnazio Danti who also worked at the Gregorian Reformation of the Calendar (1582) drafted the project of a meridian line, which would have been the largest in the World, his untimely death on 22nd October 1586, 40 days after the translation of the obelisk, delayed this work of 230 years. Only in 1817 Cardinal Peter Maccarani, with the astronomer rev. Filippo Luigi Gigli, realized the line in granite, 7cm wide and 70 meter's long from Cancer to Capricorn. The characteristics of such line are measured and reported in this paper, they have been used as zero calibration of the instruments in the measurements of the Earth's rotation period.

2. The stellar aberration

Published in 1727 as a discovery of a new motion of the fixed stars, by the Royal Astronomer James Bradley, the stellar aberration moves the stars around an ellipse. The ecliptic longitude of the Sun determines the longitude's aberration amount for a given star: it is maximum ± 20.62 arcsec if the star is on the ecliptic plane, and with the Sun in conjunction or opposition, it is zero in both quadratures. Out of the ecliptic plane a latitude component appears, which equals the longitudinal one at the ecliptic pole, where γ Draconis, the star observed by James Bradley, it is located. We observed Antares between 130° to 100° from the Sun and Ras Alhague in evening, twilight and sunset conditions; the aberration is proportional to the difference of the cosine of such angles or 47% of the 20.62 arcsec, i.e. 9 arcsec. A difference in 9 arcsec is corresponding to 0.6 s in transit time, with respect to a constant sidereal day. In 30 days, as the duration of this series of observations, it corresponds to a drift in the duration of the sidereal day of +0.023 s/day.

The aberration value of 9 arcsec corresponds to twice the parallax maximum estimated error of 4.5 arcsec (corresponding to 2 mm on the meridian line at 92 m from the gnomon on the Capricorn's disk).

2.1. *Reducing the parallax error*

A mirror located in the center of the meridian line, always in the same point, is aimed with the monocular at its center. The top of the obelisk is at 92 meters of distance, and an error of pointing of ±2 mm is possible, this yield a maximum angular uncertainty of ±4.5 arcsec.

3. The observations at the meridian line of obelisk's occultations: A differential measure

The inclination coefficient 235.872 s = 3 m 55.872 s is the difference with 24 hours of the measured average sidereal day. The event measured is the disappearance of Antares behind the obelisk, called *first contact* behind the obelisk.

The figure 1 represents the linear fit of the UTC transit times observed with a monocular as ingress and egress time behind the obelisk, as seen from the same point of the end of the meridian line next to the Capricorn sign. The average sidereal day is 23h 56m 04.128s ±0.02, which is +0.038 ±0.02 s larger than the standard value for it. The special relativistic effect +0.0207 s is within a sigma from our result.

These measurements are made all from the same place of the meridian line, near the black star of the Capricorn's disk for Antares and Venus (in afternoon meridian transit during its Eastern solar elongation) and near the black star of Virgo's disk for Ras Alhague, so they are differential. Systematic deviations along the meridian line do not affect them.

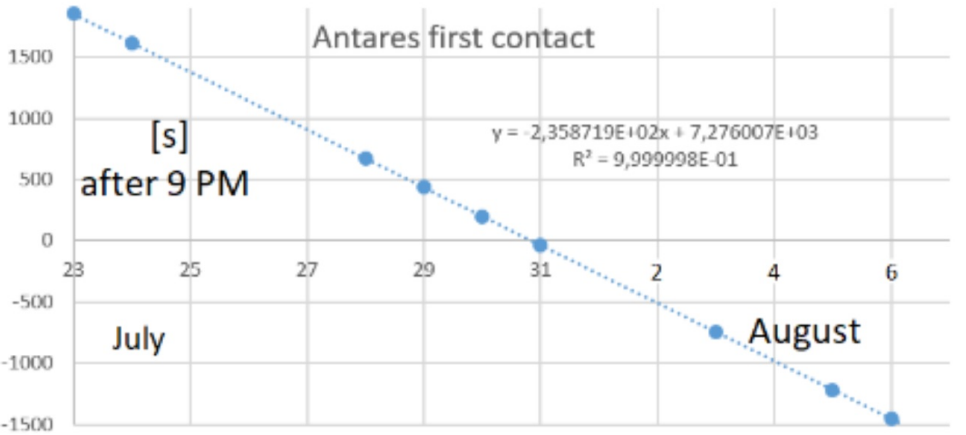

Fig. 1. The average sidereal day from 23 July (Sun $\lambda = 121°$) to 21 August 2021 (Sun $\lambda = 149°$). Antares has $\lambda = 250°$. In this timespan the ecliptic elongation of Antares from the Sun ranges from $\lambda = 129°$ to $\lambda = 101°$. The difference of the cosines is 0.2, multiplied by 20.6 arcsec, the aberration constant, yields 9 arcsec, which in time is 0.6 s. In the 29 days of this plot the theoretical value is is 0.0207 s/day, and the measured one is 0.038±0.02 s/day.

4. Local deviations from the North of the meridian line

A general astrometric recognition of the meridian line has been done on the zodiacal disks, obtaining the following deviations with respect to the axis of the obelisk.

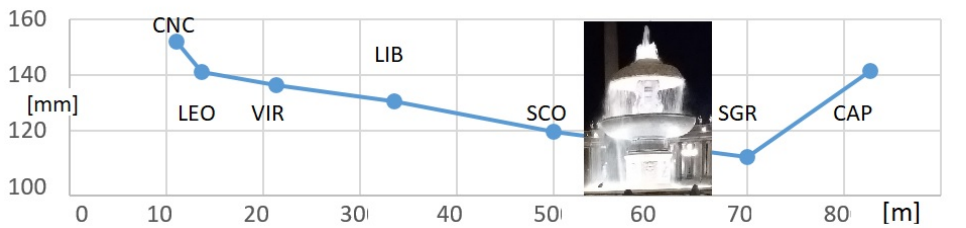

Fig. 2. Deviations in mm from the obelisk's axis along the line.

The cross on top of the obelisk is not aligned with its axis, being slightly west. The cross has been probably used for aligning the Capricorn with the Summer signs. They are at the same westward distance from the obelisk axis, being aligned with the celestial North within 2 mm along 71 meters, which corresponds to 6 arcseconds: the top of the technology of 1817.

5. Orthogonality of the cross over the obelisk

After calibrating the meridian line with respect to the North, it is possible to calibrate the gnomon (the obelisk with the cross) with respect to the vertical of its axis.

Fig. 3. The Southern face of the obelisk in full Sun: on the top the dark Southern arm if the cross is slightly on the left from the obelisk's axis.

The technique consists in measuring the difference between the observed transit and the calculated one, and transforming it into linear distances with the local velocity of the shadow. A series of observations made from October 16 to November 11, 2021 has been made to verify the orthogonality of the cross above the obelisk, and its symmetry axis. The Sun, as seen from the star of the Scorpio's marble zodiacal disk, started to pass behind the top of the cross, and it scanned all the features (cross, star, mounts, pyramid and the uppermost sections of the monolith). The instant in which the Sun passed through their symmetry axis was compared with the transit time calculated with the ephemerides. After many verifications in St. Maria degli Angeli meridian line to the nearest arcsecond, the ephemerides of Stellarium 0.20.2 have been used for St. Peter's square meridian line. The final result of this study has an uncertainty of $\pm$ 3 mm, due to the location of the telescope or of the camera, in case of direct vision, on the marble disk.

With respect to the symmetry axis of the obelisk:

- the axis of the obelisk from the point is defined (10 and 11 November)
- the star is 16.5 mm West of the axis (20 October)
- the middle part of the cross is further 10 mm West (18 October)
- the uppermost part of the cross is further 5 mm West (16 October)

Being the errorbar $\pm$ 3mm the cross can be vertical as well as slightly inclined. The four tyrants have the function of stabilization during windy days. On 14 october, a windy day, the oscillations of the cross have been detected. The cross

Fig. 4. The Sun at noon on November 10, 2021, as seen from the Scorpio's black star.

is 90 mm wide and the oscillation were 5 mm - 10 mm. All the structure on top of the obelisk is 5 meter high, then the oscillations are small. The orthogonality of the whole structure verified from 64 m, has an angular accuracy of $\pm\ 10''$.

6. Discussion and conclusions

The measurement of the length of the sidereal day with a fixed star is not a simple experiment. It is necessary to have a fixed instrument and a very low parallax. The Vatican obelisk was the fixed reference frame used for this experiment, and the parallax was reduced by observing from the center of the granite meridian line of St. Peter's square. A mirror was used to aim at the same point of the line, to reduce the parallax down to 4 arcsec. The final result over 31 days on Antares from 21 July to 21 August 2021 allowed to detect the contribution of Special Relativity as stellar light aberration within less than a sigma (0.02 s) of the predicted theoretical value of the average sidereal day: 23h 56m 04.138 s $\pm$0.02 s, 0.0273 s larger than the aberrated value.

An extremely good result obtained with such historical instrument, the obelisk-meridian line of St. Peter's in the Vatican. A monocular, a mirror and a UTC synchronized watch and an audio-recorder has been a light equipment to perform such an experiment. The didactic value of this experience is paramount.

The deviation of the line from North and of the obelisk with the uppermost cross with the vertical are measured with a few millimeters accuracy, by comparing the transit's timings with the ephemerides.

Betelgeuse, Sirius and the stars in the roman *Settecento*

Costantino Sigismondi
ICRA, Sapienza University of Rome,
Rome, Italy
E-mail: sigismondi@icra.it
http://www.icra.it/solar

Betelgeuse was reported as a magnitude "1-" in the Almagest of Ptolemy (150 AD), while it is of first magnitude star in the Uranometria of Bayer (1603). The latter with the stellar catalogue of Philippe de la Hire were used to include in 1701 the stars in the Great Meridian Line of St. Maria degli Angeli by Francesco Bianchini (1662-1729). For Sirius and Arcturus a series of star were positioned on the floor of the Basilica in correpondence with their positions up to two hours before their meridian transit, with 15 minutes of interval in the case of Sirius. Other stars in the floor represent the motion of the Sun on 20 August 1702 and in the Equinoxes, so that since two hours before the meridian transit it was possible to see how the Sun approached the Celestial Equator. Their astrometrical calibration with the Sun along the year is here published for the first time: for some of the stars the timing accuracy of their location is within a few seconds, as well as their distance from the pinhole, while in other cases it may reflect the "quantization" due to the terracotta bricks on the former floor of the Basilica. Because of the precession and proper motion the position of Sirius on the line changed from 1701 to 2021, and it has taken into account in this analysis. The black marble stars of the Vatican obelisk meridian line (1817), are calibrated with respect to the 3D star on top of the obelisk, by projecting the Sun behind it through a 7×18 prismatic monocular.

Keywords: Betelgeuse; Stellar Variability, History of Astronomy, Meridian Line, Santa Maria degli Angeli, Vatican obelisk, Rome, Francesco Bianchini (1662-1729).

1. Positional astronomy in 1700 in Rome

During the *Settecento* in Rome the research in astronomy was dedicated to Celestial Mechanics,[1] as in the other Eurpean Countries. In the various observatories present in Rome (the Jesuits at the Collegio Romano, the Dominicans at Minerva, Bianchini in St. Maria degli Angeli) the measure of their geographical coordinates with lunar eclipses was performed and compared with the other European cities. A lunar occultation was firstly observed by Giovanni Battista Audiffredi at Minerva, the one of Spica, with evidence of multiple nature of this stellar system. This observation was realized in view of a better knowledge of the lunar orbit. Francesco Bianchini (1669-1729) in St. Maria degli Angeli observed also three lunar eclipses in 1703 in order to verify the lunar theory in the Gregorian Calendar, and we used them to recover the UTC of the solar meridian transits. The coordinates of the stars used to measure the solar longitude were taken from the Catalogue of Philippe de la Hire (1700), of the Observatory of Paris. Bianchini placed 22 stars on the marble of the meridian line st. Maria degli Angeli, and Bellatrix, the western shoulder of Orion, or γ Orionis and Betelgeuse, the oriental one, are reported with their magnitude in

figure 4. Two of the stars have been found in the wrong place: both of the Northern hemisphere, placed in the Southern hemisphere. The reason was a misreading of the coordinates in the book of Philippe de la Hire, like if that work was hurried, without any time for revision. Other stars have been placed with an extreme care and precision, like for Sirius.

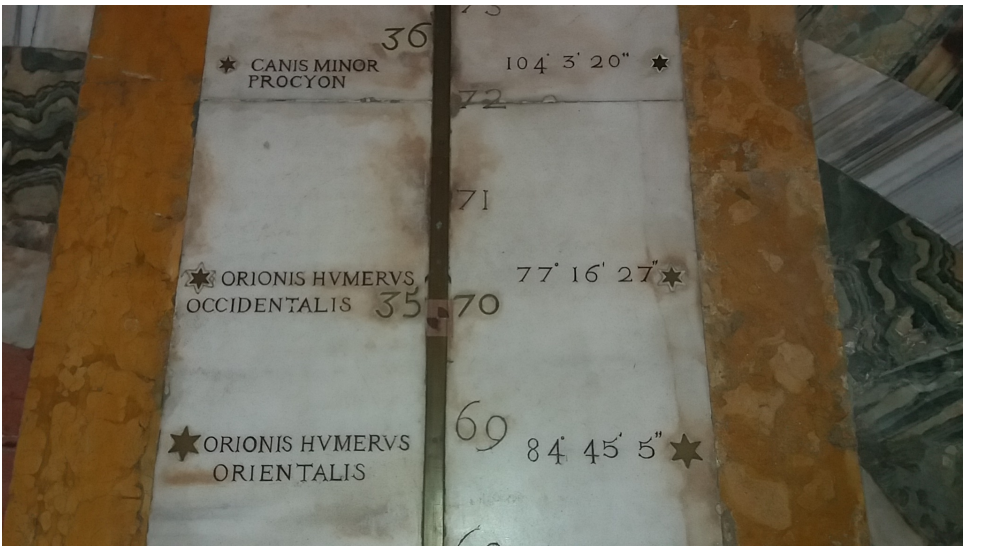

Fig. 1. Procyon, Bellatrix (occidentalis) and Betelgeuse (orientalis) on the meridian line of St. Maria degli Angeli, with their magnitude. Bellatrix is smaller than Betelgeuse. 35° is the zenithal distance of Bellatrix, $70 = 100 \times tan35°$.

2. Magnitudes and stellar positions in St. Maria degli Angeli

Bianchini wanted to represent the zodiacal signs with the corresponding constellations of the Atlas of Johannes Bayer, the Uranometria (1603). Francesco Tedeschi realized the marble *tarsie* and Bianchini provided the magnitude's scale according the Catalogue. Also on the meridian line the magnitudes were attributed according to that Catalogue, not being stellar variability still recognized as a general property of the stars.

The position of Sirius on the meridian line is the one of 1700 "precessioned" to 1701. The precession was the only one motion of the celestial sphere to be known at that time. The proper motion was discovered by Edmund Halley on Arcturus' coordinates few years later in 1718. The stellar aberration, which is annual, was discovered by James Bradley in 1727 on γ Draconis.

If we compute the position of Sirius with the coordinates of today, applying the precession down to 1701 we do not found its position on the meridian line, because of its proper motion in declination of 1.211 arcsec/year Southwards, which

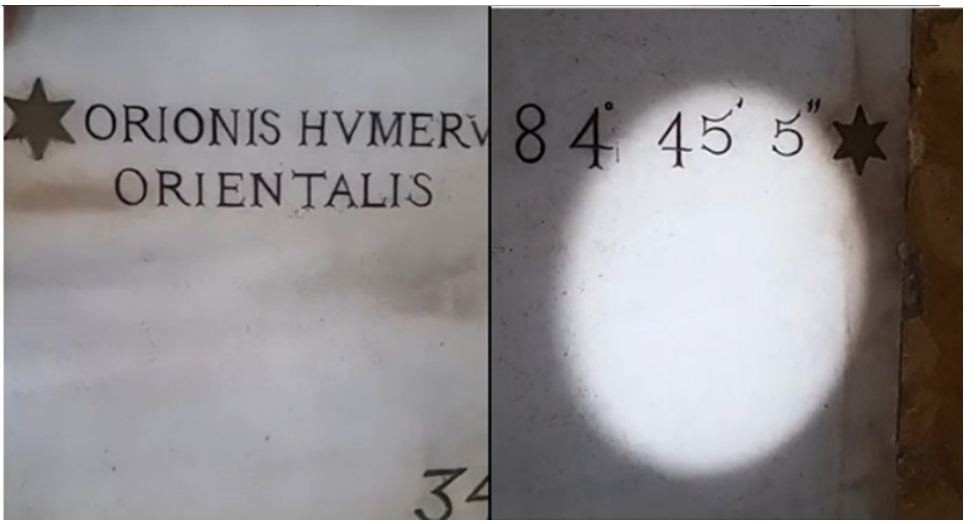

Fig. 2. The Sun passing over the position of Betelgeuse in the spring of 2018. The ecliptic longitude $84°45'5''$ of 1701 is reported on the meridian line, in correspondence of its declination $34°$ is the zenithal angle of the Northern limb of the Sun at the moment of the photo.

Fig. 3. The star of the celestial North pole in the Basilica of St. Maria degli Angeli.

in 320 years totalized 387 arcsec, i.e. 0.68 centesimal parts or 137 mm towards the Capricorn sign.

The positions of the stars of series of Sirius, on the hyperbola of Sirius' path on the floor of the main hall, the original roman hall of 30 meters of heigth, have been placed to mark each 15 minutes the approach of Sirius to the meridian line.

Fig. 4. The ellipse of 2100 orbit of the Polaris, around the North Celestial Pole.

Fig. 5. The constellation of Leo at the meridian line of St. Maria degli Angeli, represented with its stars and corresponding magnitudes, according to the Uranometria (1603).

Excepted the star of -2 hours, which is absent without signs of effraction, all other stars are placed within 10 seconds of accuracy, from the actual time of meridian transit. This verification has been realized on February 5 and November 8 2021 by observing the Sun transiting on the same path. Knowing the instant declination of the Sun, also the distance from the pinhole's vertical has been verified.

As example I report the observations of the star 1 hour 45 minutes, 45 and 30 minutes before the meridian transit on November 8th 2021.

- first contact 10:08:12 – 11:08:10 – 11:22:34.5
- last contact 10:09:42 – 11:09:40 – 11:24:02
- star inside for 01:30 – 01:30 – 01:27.5

The conjunction was respectively at 10:08:57, 11:08:55 and 11:23:18.5 and the solar meridian transit occurred at 11:54:04, then with an advance respectively of 1h45m07s 45m09s and 30m40s. The time difference was -7, -9, and -40 seconds. The 30 minutes-before star shows a wrong position in timing (azimuth) but a correct position in declination (distance from the pinhole's projection) since the duration of the timing is nearly constant (90 s) or compatible with the motion in declination of the Sun during 1h 15 min of 0.86 arcminutes.

Moreover the solar transit lasted 2 m 21 s, and the transit over the star 1 m 30 s, this meant that the center of the star was separated by the solar one by 33 s (see fig.1).

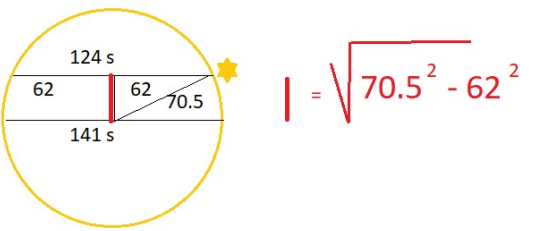

Fig. 6. The theorem of Pitagora can be applied on the solar ellipse, because the properties of its chords are preserved in the projection on the floor of the Basilica. The data are of the meridian transit of 7 Novembre 2021: 141 s is the transit's duration and 124 s is the time of Sirius star inside the solar moving ellipse on the floor.

By using the same technique to the ten stars of Sirius all over the floor of the Basilica we found the stars with azimut (timing) errors of 7 to 40 seconds, or 5 cm to 16 cm, while the declination (distance from the pinhole's vertical point) is correct, since the duration of the contacts of the solar limb with the stars is constant.

The azimuthal dimension of 14 cm, is compatible with the presence of terracotta bricks on the ancient floor of St. Maria degli Angeli, the one realized by Michelangelo.

3. Equinoctial line and Papal path of 20 August 1702

It seems like the stars, originally, were all placed at the center of the closest terracotta bricks, placed with the long side parallel to the main hall of the Basilica. Another way of describing that fact is that 11 bricks were prepared with a star in

Fig. 7. The Sun on the meridian line at Sirius' declination on November 7th 2021. The star is included in the solar image. It transit lasted 141 s and the "time of flight" of Sirius was 84 s.

Fig. 8. The solar image "climbs" the column of Vanvitelli on November 7th 2021.

the middle, and later they were used to substitute the selected bricks by the actual path of Sirius. The stars of the Celestial Equator show an alignment not exactly perpendicular to the meridian line, by two arcminutes, or 11 mm over 20 meters, the timings are accurate. It may reflect the use of a "paleo" meridian line which

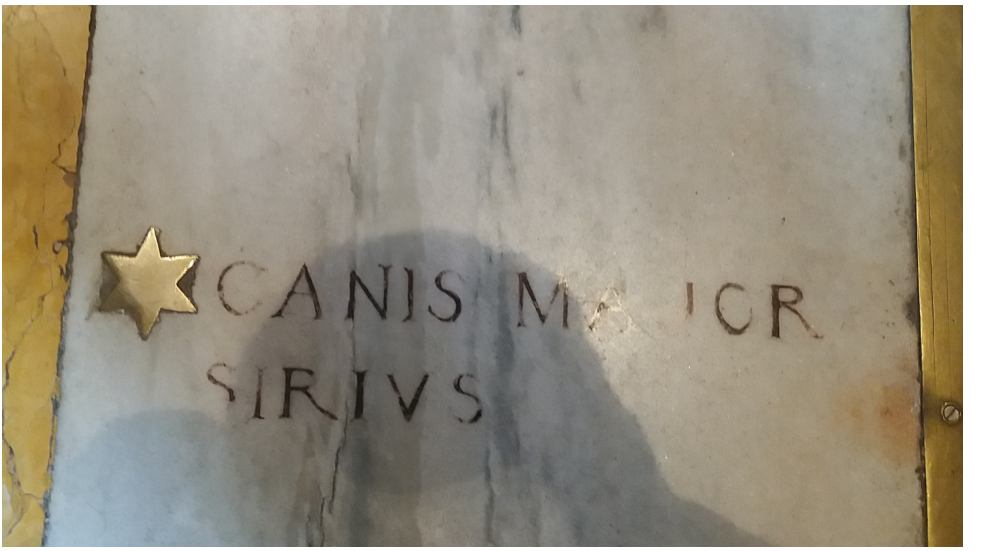

Fig. 9. The star of Sirius on the marble *Imetto* of the meridian line.

Fig. 10. The Sun four minutes before the meridian transit of 8 November: its position with respect to Sirius' star is nearly tangent. With respect to 7 Nov 2021 the Sun is 16.5′ more South, about 50% of its diameter. This image, with the one of figure 6, account for this fact precisely, being a differential measure. The Sun moves perpendicularly to the brass line.

was better aligned with the North than the present one, modified after the intervent of Giacomo Filippo Maraldi, an astronomer of Cassini's observatory visiting Rome when Bianchini was tracing the Great Gnomon. He had his own observing place in the Tower of Biscia in Palazzo Venezia, from which he transmitted the visual

signal to S. Maria degli Angeli. The boreal line, 6 meters long and a few months "older" than the Great Line, was used by Bianchini only to measure the latitude of the pinhole, and later abandoned, but it was better aligned to the North than the Great one. This would explain the 2 arcminutes of shift of the Equator, materialized by the alignment of four stars placed each 30 minutes before the meridian transit.

For the stars of the papal path the accuracy on their location is slightly better than of Sirius, but always a few cm of difference with respect to the theoretical positions are found.

Fig. 11. One of the stars of the solar phat of August 20, 1702, when the pope Clement XI visited the meridian line. Photo of August 19, 2021.

4. Marble disks in St. Peter's square in 1817

Their location on the meridian line is connected with the top features of the obelisk. The marble is really of fine quality, offering a very good reflection to the projected image through a telescope. Also the chromatic aberration is well visible.

Fig. 12. The star of Scorpio on the meridian line of St. Peter's square. The line was realized in 1817, the director of the works and committent was Cardinal Pietro Maccarani, head of the Fabric of St. Peter. The art of marble *tarsie* was still at its apogee. Photo of 20 October 2021.

5. Conclusions and Perspectives

The stars of St. Maria degli Angeli described in this text are important to understand the technology used to place them, owing their astronomical significance. The verification of their positions requires still more observations, because on 5 February and 8 November 2021 not all stars were measured. Better data are available for 19 August 2021 for the stars of the papal visit. Has Bianchini placed the stars, and

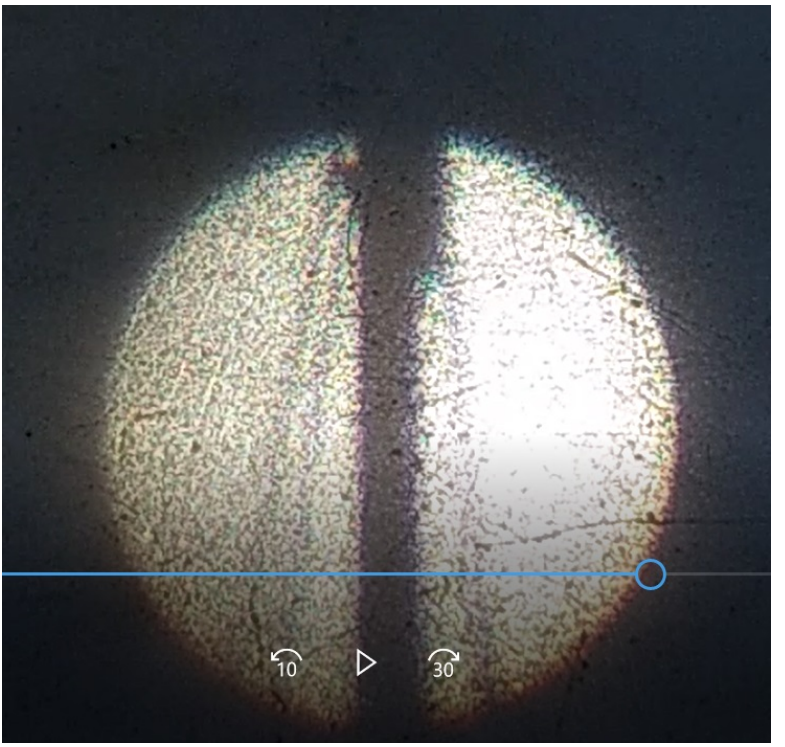

Fig. 13. The Sun projected on the Scorpio marble on October 18, 2021, at the meridian transit: the central part of the uppermost cross is visible.

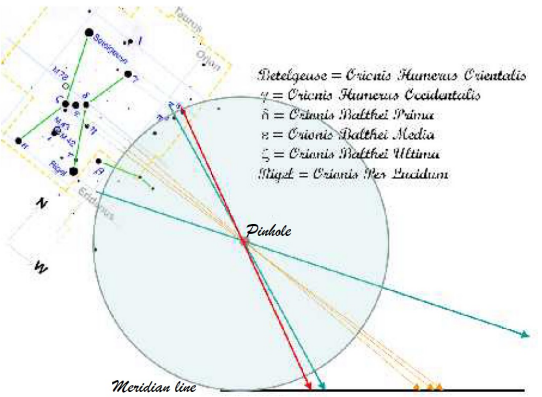

Fig. 14. The projection of the stars of Orion along the meridian line through the pinhole.

Fig. 15. A star on the floor of St. Peter's Basilica.

Vanvitelli left them in the same place? Has Bianchini placed the stars of Sirius in the center of the bricks and then changed only the relevant ones? Or was continuous the position of the stars on the floor of the Basilica since the inauguration of the meridian line in 1702?

In the Vatican the stars on the meridian line of St. Peter's square and the stars on the obelisk belong to different centuries: nineteenth and sixteenth one. Pope Sixtus V placed some obelisks in the squares of Rome (Laterano and Piazza del Popolo and St. Peter's square) as well as the one of St. Maria Maggiore. On the top of these obelisks a three-dimensional star is always present. It is like the crossing point of all the direction, a geodetic point near each relevant point of the Urbs. Sixtus V was the ruler of the urbanistic of Rome, and its plan is effective still nowadays. I presented here the observations in St. Peter's square made with a small telescope, like the one that Bianchini used in the Basilica of St. Maria degli Angeli to observe the stars transiting through the window over the pinhole. The sidereal period of the Earth's rotation was recovered to the nearest 1/100 s, by using the vatican obelisk

Fig. 16. Before and after the solar meridian transit, as seen from Scorpio on November 10, 2021.

Fig. 17. The ghost image of the Sun behind the three-dimensional star superimposed to the obelisk's profile, and its nearly 100 m-long shadow at 10:40 AM on November 18, 2021. Both the Sun and its halo are overexposed, and only the ghost image holds the solar position's information.

Fig. 18. The Sun projected near the Scorpio's star (left Oct 20, 2021, -20 s transit's advance) and Sagittarius' star (right: Nov 18, 2021, -27.8 s). The connection between the star and the solar occultation by the three-dimensional star above the obelisk is not given by the dates reported on the zodiacal disk, but there is a 3-5 days anticipation, due also to the concave shape of the square.

Fig. 19. The dimension of the solar image projected on November 18, 2021 compared with 0.50 euro. The mini-telescope has 7 x magnification, with respect to a pinhole image. This image was projected at 300 mm of distance from the telescope's objective. The pinholhe image would have sized 3 mm (always 1 to 100 the ratio diameter:focal length of the solar image). Then the image is 21 mm of transverse diameter. The meridional diameter is rather 2 times the transverse one.

as sighting reference. This technique has been adapted also to hazy days, when the image cannot be projected to the marble: a direct vision of the obelisk is realized as in fig. 16. The calibration of the line with respect to the celestial North, and of the obelisk and the uppermost cross with respect to the vertical axis of symmetry of the obelisk is another fine technique, to inspect the details of the wonderful manufacture of about two millenia B. C. the obelisk from Heliopolis, dedicated to the Sun healer from blindness. Art, religion and science are profoundly entangled in this approach to the stars in the roman *Settecento*.

Fig. 20. The comparison between the direct image (overexposed halo) and the ghost image, on November 17, 2021 behind the Northern fountain's water. The top of the obelisk, as seen from the meridian black star is visible, also in the left-down pane, where the Sun's halo saturates most of the image, and some water's droplets appear black. The instant of the meridian transit was chosen for this screenshot, as the green ghost image shows, being divided into two equal parts by the top cross. The meridian transit occurred at 11:54:41, 28 s before the ephemerides' one at 11:55:09. The use of the small telescope allowed to reach always a timing accuracy better than one second. The offaxis angle of the telescope was evaluated by the motion of the projected image in term of the solar angular diameter of $32.4'$ entering the Sagittarius. The lens is placed on the meridian line axis within 0.5 mm. The transit lasted 2 min 16 s, $\varnothing_\odot = 32'\ 05'', 16''$ less for Nov 18.

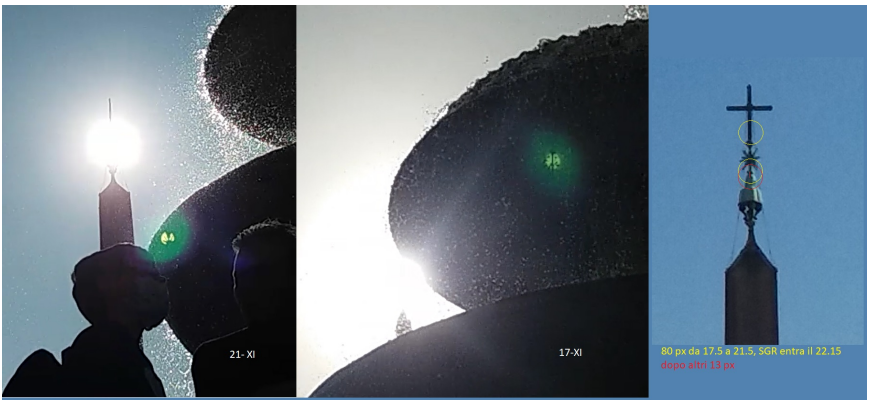

Fig. 21. The Sun filmed from the Sagittarius' black star on November 17 (center) and 21st (left). The position of the Sun is reported on the cross on 17 November and below the 3-D star on 21st. The red circle is where the ingress in Sagittarius occurred on 22.15 November 2021.

Fig. 22. The Sun at 12:07:40 of 4 December 2021, 8 minutes after the meridian transit. The yellow empty disk represents the position of the Sun at the meridian, and the red one the position at the Winter solstice of December 21, 2021. The photo is taken from the zodiacal marble disk of the Capricorn, on the black star. The alignment between the Sun at the solstice and the 3-dimensional star is confirmed as in the other austral zodiacal signs of Scorpio and Sagittarius.

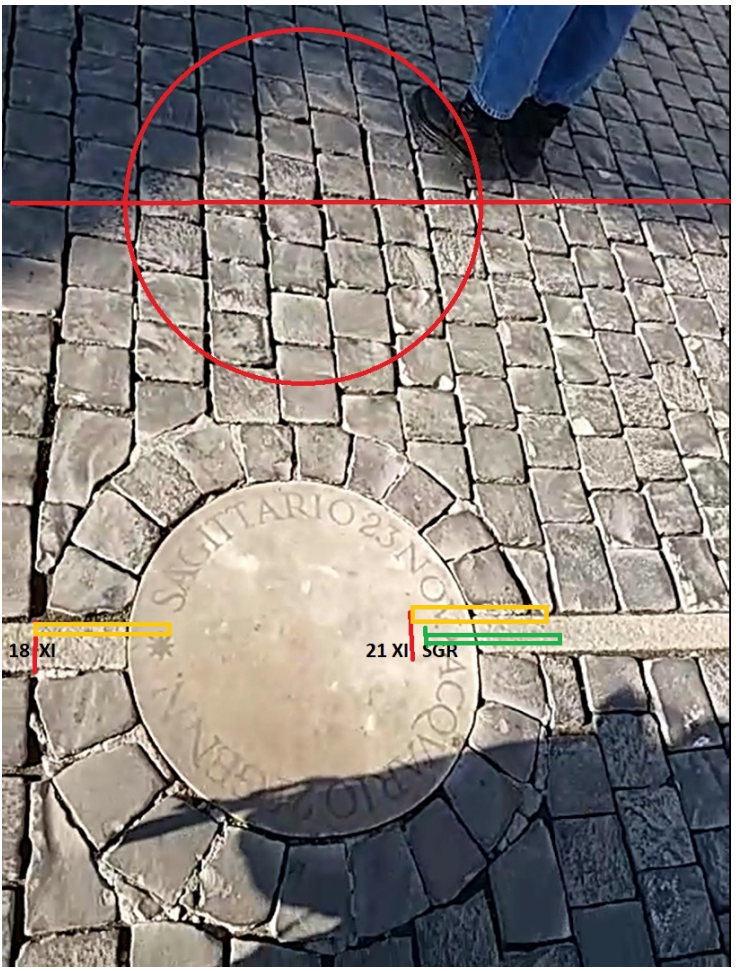

Fig. 23. The principle of the shadow's motion perpendicular to the meridian line around the meridian transit has been used to draw this image: the red line and circle are used to predict the position of the Sun 25 minutes later at the meridian transit: the Sun disappears at the ground level at the two extremes of the meridian diameter. Then the Sagittarius' marble disk has been located in the sole point were the Sun could illuminated all the disk's meridian diameter at the ingress of Sagittarius. The photo is of Sunday 21 November 2021, 16 hours before the ingress of the Sun into Sagittarius, and 30 minutes before the papal Angelus.

†E-mail: jorge.cervantes@inin.gob.mx

It is commonly known that the steady-state model of the universe was proposed and championed in a series of influential papers around mid-twenty century by Fred Hoyle, Hermann Bondi, and Thomas Gold. In contrast it is little known that, many years before, Albert Einstein briefly explored the same idea; that is of a "dynamic steady state" universe. In 1931 during his first visit to Caltech, Einstein tried to develop a model where the universe expanded and where matter was supposed to be continuously created. This latter process was proposed by him to keep the matter density of the universe constant. However, Einstein shortly abandoned the idea. The whole event has already been described and analyzed by C. O'Raifeartaigh and B. McCann in 2014. It is the purpose of this brief note to point out what might have prompted Einstein to consider a continuous creation of matter and the prevailing circumstances at that time that drove Einstein's intent.

Keywords: History of Physics; Cosmology; Einstein.

1. Introduction

The first relativistic model of the cosmos is due to Einstein. His model entailed the idea of a universe both isotropic and homogeneous on the largest scales (idea known as "Cosmological Principle"). At that time, it was the accepted view that the universe was stationary. This was not unreasonable since relative velocities of stars are small. To achieve a stationary universe, Einstein added in 1917 to his original field equations, the so-called cosmological constant "λ" to counterbalance the effects of gravity and attain a static universe[1]:

$$G_{\mu\nu} - \lambda\, g_{\mu\nu} = -\kappa \left(T_{\mu\nu} - \frac{1}{2} g_{\mu\nu} T \right) . \tag{1}$$

Einstein showed that the value of the constant he introduced was proportional to the mean mass density ρ of the universe and inversely proportional to the square of R, its radius of curvature,

$$\lambda = \frac{\kappa\rho}{2} = \frac{1}{R^2} . \tag{2}$$

The introduction of λ in the original field equations was accepted by the early few practitioners of General Relativity as convenient to keep the current standard view at the time, of a static universe.

However, Einstein was uneasy with his forced introduction of the λ constant. Several of his papers show his uneasiness. For instance, in a 1919 publication Einstein stated:

"...the general theory of relativity requires that the universe be spatially finite. [This] requires the introduction of a new universal constant λ, standing in a fixed relation to the total mass of the universe (or respectively, to the equilibrium density of matter). This is gravely detrimental to the formal beauty of the theory".[2]

It was not until 1931 that Einstein at long last dropped off λ from his field equations. During those days, Einstein was visiting professor in Pasadena California attending an invitation made by Robert Andrews Millikan to spend a short season at Caltech (from late December 1930 to early March 1931). Soon after his arrival to California he discussed Hubble's redshift measurements and its implications with Mount Wilson Observatory astronomers.

Today there is still a justified widespread view that Einstein discarded the cosmological constant immediately after he was satisfied of the validity of Hubble's evidence for a non-static universe. This rendered λ in his field equations, redundant. In April of that same year, Einstein submitted for publication, a paper to the Sitzungsberichte der Preussischen Akademie der Wissenschaften where he rejected his cosmological term as superfluous and no longer justified. In his own words, "theoretically unsatisfactory".[3]

But the view that Einstein dropped off λ just before his meetings with the Mount Wilson astronomers (in early Jan 1931) is not strictly exact. In the interval between his arrival to California and his 1931 Sitzungsberichte paper (April 1931), he made a last effort to model a "dynamic steady state" universe, keeping λ in his field equations. This was serendipitously discovered in 2013 by Cormac O'Raifeartaigh in an unpublished Einstein's manuscript kept in the Albert Einstein Archives (AEA) maintained by the Hebrew University of Jerusalem.[4] The first translation into English of the manuscript, contents and its analysis, has been already covered in 2014 by his discoverer Cormac O'Raifeartaigh and his colleague Bruce McCann.[5] In addition, the manuscript contents were also commented in a note added in proof by Harry Nussbaumer and later also reviewed by him.[6,7]

2. A significant finding

The discovery by O'Raifeartaigh of the unpublished manuscript showing a model still using the lambda constant, came as a great surprise to everyone. From the moment Einstein arrived at Caltech it seemed that he had already accepted a non-static universe. Various reports in the local press affirm this. And consequently, people supposed that Einstein had already scrapped the constant from his field equations as unnecessary.

As a celebrity, during his visit to California, Einstein's activities and sayings were reported daily by the press. In Jan 3 the New York Times (NYT) reported that during an interview given the previous day Einstein stated: "New observations

by Hubble and Humason (astronomers at Mount Wilson) concerning the red shift of light in distant nebulae make the presumptions near that the general structure of the universe is not static".[8] The next following month the NYT (Feb 5) another front-page story, informed that Einstein delivered a lecture the previous day (Feb 4) where he no longer held to the model of "Stable universe".[9]

On January 15, Einstein attended a welcome dinner in his honor at "The Athenaeum", a club house for the California Institutes Associates (a group of promoters of southern California scientific and scholarly research). The dinner was attended by around 200 guests among them a selected group of astronomers that had collaborated with their own research in testing relativity.[10] The final dinner speech was delivered by one of them, Walter S Adams, director of Mount Wilson. Adams had verified Einstein's prediction of gravitational redshift.[11] During his speech Adams highlighted the problem of the "nature and structure of the universe" and he announced that:

"Professor Einstein is now inclined to consider the most promising line of attack on the problem to be based on theories of a non-static universe, the general equations of which have been developed so ably by Dr. Richard Chase Tolman, of the California institute of technology".[12]

Despite the multiple examples that can be cited, affirming Einstein's alleged intention to follow a non-static approach, the 2014 discovery by O'Raifeartaigh of the manuscript, revealed that Einstein temporarily followed a different scheme in his unpublished document.

3. The manuscript

The unpublished manuscript is entitled "Zum kosmologischen Problem", that is located in the Albert Einstein Archives (AEA) (draft, 1931. Doc [2-112]). It is a signed, four-page handwritten manuscript by Einstein on American paper. Assigned by AEA to January or February 1931.

The cosmological model depicted in the manuscript was not previously detected given that the first words of its title are identical to those of Einstein's 1931 Sitzungsberichte paper (April 1931). For this reason, it was assumed to be a draft of the latter publication.

The manuscript has already been extensively analyzed by O'Raifeartaigh and colleagues[13] and in the here cited papers by Nussbaumer, so we shall limit ourselves to giving a succinct description of its contents based on those publications.

4. The model in the manuscript

In the manuscript Einstein explores a solution to his field equations retaining λ that could be compatible with Hubble's observations; to be precise an expanding universe in which the density of matter does not change over time. Einstein starts his analysis by choosing the metric of flat space expanding exponentially (De Sitter

metric):

$$ds^2 = -e^{\alpha t}(dx_1^2 + dx_2^2 + dx_3^2) + c^2 dt^2. \tag{3}$$

So, the distance between two points increases over time as $e^{\alpha t/2}$, and he remarks: "one can thus account for Hubbel's [sic] Doppler effect by giving the masses (thought of as uniformly distributed) constant co-ordinates over time".

In his calculations he finds that α^2 (representing the expansion of the universe) is related to its overall density ρ as,

$$\alpha^2 = \frac{\kappa}{3}\rho. \tag{4}$$

That is, ρ determines the expansion. Since the redshift measurements at the time suggested that the universe expansion is constant, so he concluded that the density must be constant as well.

In the final part of his manuscript, Einstein proposes that the density of matter remains constant by supposing a continuous formation of matter in empty space. He then observes that: "For the density to remain constant, new particles of matter must be continually formed within that volume from space."

At the end of the manuscript, he associates the cosmological constant with an energy of space: "by setting the λ-term, space itself is not empty of energy". Consequently, the continuous creation of matter becomes associated to the λ cosmological constant.

Einstein's "dynamic steady state" universe simultaneously incorporated the observed expansion of the universe together with a new paradigm, namely of an expanding universe that maintained its isotropy and spatial homogeneity the same as it always has and always will (later dubbed the perfect cosmological principle) by means of the continuous creation of matter.

The "dynamic steady state" model was so compelling to set aside. However, Einstein didn't submit his manuscript for publication. O'Raifeartaigh and colleagues detected the possible reason why Einstein gave up publishing it.[13] He must have noticed on revision, that his model contained a flaw. Once the error is corrected the model leads to the trivial solution $\rho = 0$, that is an empty universe of matter. Therefore, he promptly abandoned this attempt.

We must ask now what it was that attracted Einstein to consider the possibility of a universe where there is a continuous creation of matter. To find a possible answer we shall consider the reception at that time, of an expanding universe as opposed to prevailing static views.

5. Universe's age and Earth's age tension

Towards the beginning of the 1930s the main objection to the interpretation of the Hubble constant as the indicator of the universe expansion was that it's measured value implied a younger universe than that of Earth's accepted age.

Before 1930's, scientific estimates of the age of the Earth dated from mid-19th century, from Helmholtz-Kelvin gravitational contraction ages,[14] passing through those resting on geology (i.e., the amount of salt in the oceans, sediments) and - after a fierce debate between geologist and physicists[15] - finally deferred to an age based on early-20th century radioactive dating.[16] This produced by the 1930's, an estimate of the universe age of around 4 billion years.[17]

In 1931, at the time Einstein was visiting Caltech, the matter of determining the age of the earth was not entirely resolved to the extent that the National Research Council decided to appoint a committee to investigate to settle the question.[18]

On the other hand, the cosmological age of the universe based on the universe expansion, was estimated by taking the reciprocal of the value of the Hubble constant (Hubble's time). Hubble first evaluation of his eponymous constant was of around 500 kilometers per second per megaparsec. This implied a universe's age of about two billion years, which was in a tense contradiction with the estimated age of the Earth, as just mentioned, of about four billion years. As consequence, such mismatch created room for doubt, Einstein himself included. Some critics questioned that the observed nebulae redshifts, were in fact a manifestation of the Doppler's effect. Such was the panorama that reigned in the early 30s.

This incongruity raised two possible explanations: on the one hand Hubble constant value was wrong, or on the other hand, Doppler's shift needed a novel interpretation, as it is said today "perhaps new physics".

As it is well known, the Hubble constant estimation involved measurement of distance and velocity of a variable star (a Cepheid) belonging to a galaxy in question. This involved monitoring the apparent brightness of the Cepheid variable to obtain its period. Then, using Shapley's Cepheid calibration, its absolute brightness was established and consequently the distance to the galaxy where the Cepheid was located. At that time there was little doubt on the correctness of Shapley's calibration. Also, measurement of recession velocity of galaxies even in those days, was straightforward. Spectral recordings had already achieved good accuracy. So, Hubble's constant value was in little doubt. Eventually, some astronomers pointed out that Cepheid's calibration could be slightly inaccurate as the apparent star's luminosity could be diminished by interstellar media and that had to be accounted for. It must be remembered that It was not until mid-1940's that Walter Baade identified two Cepheid types and made a major correction to Shapley's calibration and thus to Hubble's value.[19] Now we know that the problem was on the way off value of Hubble's constant at that time.

On the second possibility, that the incongruity between the ages of the earth and the universe had its origin in an erroneous interpretation of the observed redshift, Fritz Zwicky gave in 1929 an alternative explanation. Zwicky, a resident scholar at Caltech, suggested the concept of "tired light".[20] This was a hypothetical redshift mechanism where photons lost energy over time through interactions with other particles in their trajectories through a static universe. So, the more distant objects

would appear redder than more nearby ones. It is pertinent to mention that the term "tired light" was not used by Zwicky but later coined to refer to this concept by Caltech cosmologist Richard Tolman in the early 1930s in relation to the so called Tolman Surface Brightness Test.

6. Earlier dynamic stationary state cosmologies

Zwicky was not alone. There was also an academic minority that put forward similar ideas to Zwicky's explanation even before his 1929 suggestion. All these "tired light" propositions had in common the assumption that photons heading earthward, somehow interchanged with the intergalactic medium, part of their energy, thus red shifting their frequencies.

"Tired light" was championed by the few enthusiasts of steady state cosmologies. Its appeal as we shall see resides on the fact that it circumvents the standard interpretation of the redshift as an indicator of galaxy recession and thus safeguards their view of a static universe.

The Nobel laureate Walther Nernst and William Duncan Macmillan, a well-known Chicago professor, were leading advocates of a steady-state universe. What these had in common is that they presuppose the universe as eternal, self-preserving structure in which matter and radiation are constantly been transformed into one another to keep the universe in a stationary balanced state thus avoiding a heat-dead of the universe. A cosmic destiny they both abhorred.

MacMillan's supposes in his own version of "tired light": "That there is a leakage of energy from the photon [...] due perhaps to an inherent instability in the photon, or, possibly, [due] to collisions with other photons". He concludes therefore: "it is evident that the frequency [of the photon] declines with the energy, and the lines of the spectrum are shifted toward the red".[21]

In addition, he considers that the "evaporated" energy from the photon continues to exist as abundant radiant energy of "very low frequency". A kind of primitive version of the modern CMB radiation (but the latter being Black Body radiation). Then he puts forward the possibility that perhaps the "evaporated" energy "disappears into the fine structure of space and reappears eventually in the structure of the atom". In other words, he proposes a mechanism of matter creation.

Another notable hypothesis was that of the Nobel laureate, Walther Nernst, who suggested that some photons are partially absorbed by the luminiferous æther (which he accepts to exist).[22] In his 1928 essay "Phyco-Chemical Considerations in Astrophysics", Nernst outlines the notion of matter creation in his stationary universe:

"I may therefore hold fast to the hypothesis uttered by me that, just as the principle of the stationary condition of the cosmos demands that the radiation of the stars be absorbed by the luminiferous æther, so also finally the same thing happens with mass, and that, conversely, strongly active elements are continually

being formed from the æther, though naturally not in amounts demonstrable to us,...".[23]

It is worth noticing that both, MacMillan and Nernst, claim energy transfer occurs by an unknown process yet to be discovered.

The "tired light" proposal did not vanish into oblivion as alternative explanation to redshift been caused by recessional motion. As late as 1935, Edwin Hubble himself and Richard Tolman (both at Caltech during Einstein's several yearly visits) investigated the possibility that "tired light" might be an alternative interpretation of redshift.

They did that comparing the surface brightness of galaxies as a function of their redshift (applying the so called "Tolman Surface Brightness Test"[24]). According to Tolman Test, the relationship between surface brightness of a galaxy and its redshift differs in the case of a static universe from that of an expanding one. In a coauthored publication they explored this possibility.[25] In their joint paper and to simplify their analysis, they employed Einstein's static model of the universe: ... "combined with the assumption that the photons emitted by a nebula [a galaxy] lose energy on their journey to the observer by some unknown effect, which is linear with distance, and which leads to a decrease in frequency, without appreciable transverse deflection". In short, they employed Einstein's model plus "tired light". As result of their analysis, they conceded: "Until further evidence is available, both the present writers wish to express an open mind with respect to the ultimately most satisfactory explanation of the nebular red-shift" ..."They both incline to the opinion, however, that if the red-shift is not due to recessional motion, its explanation will probably involve some quite new physical principles".

7. On Einstein's arrival at Caltech

Up until now, we have seen that in the late 1920s and early 1930s, Hubble's law was commonly interpreted as a demonstration that the universe was truly expanding. However, there was still the problem of reconciling the age of the universe with that of the earth. This inconsistency, in addition to raising a reasonable doubt about the interpretation of the redshift, gave rise to the credibility of the theories of a stationary universe. For some, the appeal of a universe without evolving through time resided in that such universe has no beginning and no end, so it converts the "age of the universe" as a senseless question issue, consequently eliminating the earth-universe ages paradox.

Attempting to develop a stationary cosmological model was indeed an attractive motivation for Einstein, since it would avoid his well-known aversion to a universe that has a beginning and reinforce his well-known paradigm of a static universe. But adopting such an idea required reliable and robust observational evidence of the continuous creation of matter.

As we will see below, fresh "evidence" (that turned out to be illusory) of the continuous creation of matter emerged just as Einstein arrived at Caltech. This came

from Millikan (Einstein host at Caltech) so it must have seemed reliable to Einstein. We must remember that Millikan received the Nobel prize partly for experimentally verifying Einstein's photoelectric equation.

8. Birth cries of atoms

On the 1st of February 1931, during Einstein's stay at Caltech, a paper by Millikan and his collaborator H. Cameron appeared in Physical Review. Its title was "A more accurate and more extended cosmic-ray ionization-depth curve, and the present evidence for atom-building".[26] This paper contained what it would seem to be the experimental evidence Einstein needed, that is, observational evidence of continuous matter creation. In our opinion, it was this publication what encouraged Einstein to use the continual creation of matter hypothesis in his unpublished manuscript. So, Einstein made his last bid to keep a stationary cosmology.

Millikan's 1931 paper is the apogee of a series of publications on cosmic rays where he explores their composition and origins. But, before we comment on this publication it is convenient to recall very briefly Millikan's research on cosmic rays. During the early 20's he and his collaborators made a series of observations on board of balloons, high altitude peaks, and different geographical locations, at various latitudes and in the depths of lakes proving in his 1926 publication that cosmic rays were of extraterrestrial origin.[27] Millikan believed that his measurements proved that the primary cosmic rays were energetic photons. He also stated that cosmic rays, "...must arise from nuclear changes of some sort..." but far more energetic than any radioactive change thus far on record".

In the same 1926 paper he suggested that cosmic rays probably came from among the following three nuclear processes: a) The capture of an electron by the nucleus of a light atom, b) the formation of helium out of hydrogen, or c) some new type of "nuclear change", such as the condensation of radiation into atoms.

Regarding third suggestion he made above, we must emphasize that Millikan here raises the creation of matter from the "condensation of radiation into atoms." this idea was not his, as he himself stated in a note written by him for the journal Science in 1930.[28] In the note he recalls having in 1915 discussions on the "running down of the universe" (i.e., when the universe has reached a state of maximum entropy) at the University of Chicago with his then colleague William Duncan Macmillan (of whom we have already commented) where the issue of atom building was discussed. Millikan recalls,

"In our conversations at Chicago W. D. Macmillan constantly held out for the view that a still further step forward should be taken and that the idea of "running down of the universe" should be given up by the assumption that atom building went on in space by the condensation of radiation into atoms. He discussed his idea in detail with me in the year 1915, and in July, 1918 he published it in full".[29]

In 1928 Millikan and Cameron found that incoming cosmic rays could be grouped into three independent energy bands centered at 26, 110, and 120 (MeV).[30] They

argued that these bands are produced by the release of photons when eventually a "sudden union" (i.e., fusion) between atoms occur. To support their assertion, they observed that the center of the bands agreed respectively with 26 MeV (which is just about the mass defect of helium), 110 MeV (which is close to the mass defect of oxygen and nitrogen) and 220 MeV (to that of silicon.) So, their inference was that the three photon bands reaching the earth must be generated by the "sudden union" of: 4 hydrogen atoms fused to form helium, 14 to form nitrogen, 16 to form oxygen and 28 to form silicon". Secondary electrons, they claimed, were produced in the atmosphere by Compton scattering of gamma rays. Millikan believed that space was filled with a tenuous gas of electrons and protons (the latter he called "positive electrons"). So, to get around the "running down of the universe" he assumed that "These building stones [protons and electrons] are continuously being replenish throughout the heavens by the condensation with the aid of some as yet wholly unknown mechanism of radiant heat into positive and negative electrons".

Millikan supposed discovery of the continuous formation of matter went beyond the scientific sphere provoking the attention of among the scientific and the lay publics. In a statement made by Millikan to the press, cosmic rays were "birth cries of atoms, a Millikan phrase that achieved a good deal of currency".[31]

Regarding Millikan's 1931 publication the one which appeared on print just at the time Einstein was hosted by Millikan, this was basically a continuation of his 1928 paper including revised energy calculations that further bolstered his tenacious ideas. A short time later Arthur Holly Compton showed that not all cosmic rays were photons, but at least a large part of them consists of charged particles. This led to a debate between the two Nobel laureates. The debate went on for some time with Compton at the winning side but that's another story.

9. Final comments

Einstein before long abandoned the idea of keeping the λ constant in his field equations. In his next publication, the 1931 Sitzungsberichte paper, he does not make use of the constant anymore.[3] At the end of the paper Einstein adds some remarks about the age of the universe problem, which was quite severe without the use of the λ constant. Today we know that the problem was on the way off value of Hubble's constant at that time. Einstein signals two possible errors that may be occurring in the initial approach to the problem. First, he insinuates that the matter distribution might be inhomogeneous and that a homogeneity approximation may be illusional. Then he adds that in astronomy one should be cautious with large extrapolations in time. His first comment is surprising as it seems to indicate some reservations on the cosmological principle.

The next following winter (1931-1932), Einstein was back in Caltech for a second stay where he met De Sitter. Together they formulated a model today known as the Einstein-de Sitter universe, assuming a flat space with no cosmological constant and with an expansion velocity asymptotically approaching zero in the infinite future.[32]

This became the standard model up to the mid-1990s. This was the Einstein's last intent to produce a cosmological model.

Jayme Tiomno: Relativity, gravity, cosmology, and the Marcel Grossmann Meetings

William D. Brewer

Fachbereich Physik, Freie Universität Berlin,
14195 Berlin, F.R. Germany
E-mail: william.brewer@fu-berlin.de
www.users.physik.fu-berlin.de/∼wbrewer/index.html

Jayme Tiomno belonged to the 'founder's generation' of physicists in Brazil. He began working in relativity theory early in his career, at a time when it was not at all 'fashionable', through the influence of his early mentor, Mario Schenberg in São Paulo. When he went to graduate school in Princeton, in February 1948, his advisor there, John Wheeler, gave him a project in General Relativity, even though this was more than 4 years before Wheeler's 'turn' from nuclear and particle physics to field theory and gravitation.

Tiomno and Wheeler however soon discovered their mutual interest in meson decays, and Tiomno's Masters and PhD theses were on topics from particle physics, which remained his major field of interest for the following 20 years, during which he collaborated with Abdus Salam, among others. Only when he returned to Princeton in 1971, a refugee from the oppressive dictatorship in Brazil, did he again begin working in gravitation and field theory, having missed the 'golden age' initiated in part by Wheeler's group.

At the IAS, Tiomno experienced a renaissance of his interest in field theory, working with Remo Ruffini and others. He continued this work in the 1980's after he was able to return to the CBPF in Rio de Janeiro (which he had helped to found). His participation in the Marcel Grossmann Meetings was limited but significant.

Keywords: Physics Brazil; History of Physics; Marcel Grossmann Meetings; General Relativity; Gravitation

1. Introduction

Jayme Tiomno was born in Rio de Janeiro on April 16, 1920, the son of Russian-Jewish immigrants who had arrived in Brazil about 10 years earlier. There was nothing in his background that might suggest that he would become an eminent theoretical physicist. But his parents both valued education and saw to it that he and his siblings (an older brother, a twin sister, and two younger sisters) were all able to attend college. In the year of his birth, on Sept. 7, the Brazilian national holiday, the *Universidade do Rio de Janeiro* (URJ) was founded as the first real university in Brazil (as a collection of faculties and institutes combined from existing institutions).

After his childhood and youth spent in small cities in Minas Gerais, Tiomno's family returned in 1934 to Rio, where Jayme completed his *curso complementar* in medicine and then began studying medicine in 1938 at the *Universidade do Brazil* (UB – as the URJ was now called). In early 1939, Jayme was enrolled by his brother

for Natural History at the *Universidade do Distrito Federal* (UDF), a newer research university founded in the capital in 1935 by Anisio Teixeira, an eminent educator who was at the time Director of Education of the Federal District.

Fig. 1. (a) Jayme Tiomno, 1941. (b) Tiomno, Wheeler, Ruffini, 2001 (c) Mario Schenberg, 1937.

Tiomno qualified for the physics course, but was unable to study at the UDF because it was closed by the Vargas regime. Its physics curriculum was incorporated into the *Faculdade Nacional de Filosofia* (FNFi) and moved to the UB. Tiomno later had to decide between medicine and physics, and he chose the latter, graduating in 1941. Figure 1 shows Tiomno at age 21, when he graduated from the FNFi, and also 60 years later, with his Princeton mentor John Wheeler and his later collaborator Remo Ruffini, at Wheeler's 90th birthday in 2001; and Tiomno's first graduate mentor, Mario Schenberg, about the time Tiomno began his university career.

Tiomno entered military service, and was able to do some research with his mentor, the experimentalist Joaquim da Costa Ribeiro, and complete his *licenciatura* (teaching certificate) during the War. However, his real interest lay in theory, inspired by his Italian professor of theoretical physics, Luigi Sobrero (a former assistant of Levi-Civitá), and after the War, he obtained a fellowship to do graduate research at the Universidade de São Paulo (USP), in the department founded by Gleb Wataghin, under Wataghin's star pupil, the theoretician Mario Schenberg. The photo in Fig. 2 shows Tiomno's professors Sobrero and Costa Ribeiro as well as the teaching assistants in physics at the FNFi in May, 1942. Many of them later became noted scientists.

Tiomno spent most of 1946 at USP, studying hard to catch up in modern physics, to which he had hardly been exposed at the FNFi. After his fellowship ended, he returned to Rio in early 1947, but was then offered an assistantship with Mario Schenberg at USP, where he went in mid-year of 1947. He worked with Schenberg on formulating gravitation in Minkowski space, his introduction to relativity. The project was completed but never published, partly because relativity, and especially non-Einsteinian interpretations of gravitation, were hard to publish in 1948, and

Fig. 2. The teaching staff in physics at the FNFi, 1942. From left: Paulo Alcântara Gomes, Elisa Frota-Pessôa, Jayme Tiomno, Joaquim da Costa Ribeiro, Luigi Sobrero, Leopoldo Nachbin, José Leite Lopes, and Mauricio Matos Peixoto.

partly due to Schenberg's political difficulties, which forced him to go into exile in Europe in the following years.

Tiomno, in the meantime, on the recommendations of Schenberg and José Leite Lopes, was granted a fellowship for graduate work at Princeton by the U.S. State Department. He had to leave Brazil abruptly in early February 1948 to meet the starting deadline for his fellowship. In Princeton, he joined the group of John Archibald Wheeler, already a well-known theoretician, working in nuclear and particle physics. Nevertheless, Wheeler started Tiomno on a project involving point particles in GR (and eventually their gravitational-radiative damping). Tiomno was frustrated with the project and received little help from Wheeler (and from Einstein). Wheeler had already suggested this topic to Leopold Infeld, who in 1949 published the result with his assistant Alfred Schild.[1] By then, Tiomno and Wheeler had turned their interest to the pion-muon decay chain, and Tiomno spent the next 20 years working mainly in particle physics, apart from two collaborative projects with David Bohm – one a conformally-invariant formulation of the Dirac theory, which Tiomno only completed 12 years later; the other the inclusion of spin into Bohm's deterministic version of quantum mechanics (1955).

Fig. 3. John Wheeler and Jayme Tiomno in Princeton, Summer 1948.

When Wheeler (Fig. 3) left on sabbatical in June, 1949, Tiomno, with his fresh MSc degree, collaborated with Chen Ning Yang and David Bohm on weak-interaction physics and on relativistic quantum mechanics. He then began his PhD thesis work with Eugene Wigner as mentor. He finished his thesis in September 1950 and returned to São Paulo on October 10.

While still at Princeton, Tiomno also met Richard P. Feynman and Cécile Morette, and invited both to visit the newly-founded *Centro Brasileiro de Pesquisas Físicas* (CBPF) in Rio, which he had helped to plan and implement. He later also encouraged Bohm to apply (successfully) for the vacant chair of Advanced Physics in São Paulo (vacated by Gleb Wataghin when he returned to Italy in 1949). The young David Bohm is shown in Fig. 4, about the time that he completed his undergraduate studies.

Fig. 4. David Bohm, around 1940.

Figure 5 is a photo of a meeting at Princeton in early 1949, where several young Brazilian physicists conferred about the newly-founded CBPF in Rio, and met the Japanese theoretician Hideki Yukawa, on sabbatical in Princeton at the time. More information on Tiomno's life and career can be found in our recent biography.[2]

2. The development of gravitation, General Relativity and cosmology research after 1950

Modern gravitational physics dates from the early 20th century. Lorentz, Poincaré, Fitzgerald and others had speculated about applying the principle of relativity to electromagnetism (Maxwell theory). Albert Einstein realized the significance of those speculations and formulated his Special Relativity in 1905. Ten years later, with the help of Marcel Grossmann, he completed his General Theory of Relativity (GR), the modern theory of gravitation. After the early period from 1915–1925, when solutions to Einstein's field equations were found (e.g. by K. Schwarzschild, 1916: gravitational singularity; A. Einstein, 1917: closed, static universe; W. de Sitter, 1917: zero-density universe; A. Friedmann, G. Lemâitre, 1924/27: expanding

Fig. 5. A group of young Brazilians, together with Hideki Yukawa (behind, center), in Princeton, early 1949. César Lattes (behind, left), José Leite Lopes (below, center) and Jayme Tiomno (below, right) were the chief founders of the CBPF (Brazilian Center for Physics Research, Rio de Janeiro), which began operations about this time. At the upper right is Walter Schützer, and at lower left is Hervasio de Carvalho.

universe), Einstein began working on a unified theory of gravity and electromagnetism, and active work on GR decreased after about 1928. Some of the early contributors to GR theory are shown in Fig. 6.

In the period 1935–1955, Einstein published with N. Rosen, L. Infeld, B. Hoffmann, P. Bergmann, W. Pauli, V. Bargmann, and E.G. Strauss on some details of GR theory, and some other authors – notably J.R. Oppenheimer et al. (1939: collapse of stellar remnants) and K. Gödel (1949: stationary rotating homogeneous universe with timelike loops) also made important contributions. But only in the early 1950's did the 'great revival' of GR and its applications to relativistic astrophysics and cosmology begin, stimulated initially by J.A. Wheeler and his school (Princeton, University of Maryland, Caltech), and independently by Bryce DeWitt and Cécile Morette DeWitt (University of North Carolina, University of Texas), and in England by D.W. Sciama, C. Isham, R. Penrose, and S. Hawking (in London and Cambridge), and in the USSR by Y. Zel'dovitch, I. Novikov, and R. Sunyaev.

Fig. 6. (a) Karl Schwarzschild, ca. 1910. (b) Willem de Sitter. (c) Georges Lemâitre.

Tiomno's interest in field theory and GR was rekindled in 1966/67, when he spent a year as Associate of the ICTP (International Centre for Theoretical Physics) in Trieste (founded in 1964 by Abdus Salam, with Tiomno's active participation). While there, he reconnected with two Argentine physicists whom he had known earlier, in Rio and in London: Juan José Giambiagi and Carlos Guido Bollini. Their joint papers, especially 'A Linear Theory of Gravitation' (1970), mark Tiomno's revived interest in gravitation theory. Giambiagi, Tiomno and Bollini are shown in Fig. 7 while at the ICTP in 1966/67, and also shown are Jayme Tiomno with his wife Elisa Frota-Pessôa in Trieste at the same time. That interest was intensified during his stay in Princeton in 1971/72, after his blacklisting in Brazil by the military dictatorship. There, he interacted with Wheeler's now flourishing school. In the years 1972–75, he published 13 articles on gravitation and field theory. In addition to his two more senior collaborators, Remo Ruffini and Leonard Parker, his coauthors included the younger physicists C.V. Vishveshwara, Marc Davis, Jeffrey M. Cohen, Frank J. Zerilli, Robert M. Wald, and Reinhard A. Breuer. Many of those publications dealt with radiation – both electromagnetic and gravitational – from particles orbiting or falling into black holes; but they also included speculations on pulsars and the balance of forces on particles near black holes, as well as the possibility and properties of gravitational 'synchrotron radiation'. Figure 8 shows Tiomno and Elisa in Princeton in 1971, and also Tiomno's farewell letter to Wheeler upon leaving Princeton in June, 1972.

The text of Tiomno's letter to Wheeler when he left Princeton reads: *"We are leaving tomorrow, looking forward to a vague possibility of remaining in Rio. We were much pleased with our stay in Princeton. I have profited much from it and started a new phase of my career. Even the disagreeable dispute with a colleague has had a positive result to stress my friendship with you and to make me recover from the difficulty of writing papers. Here are some of them, which would not exist*

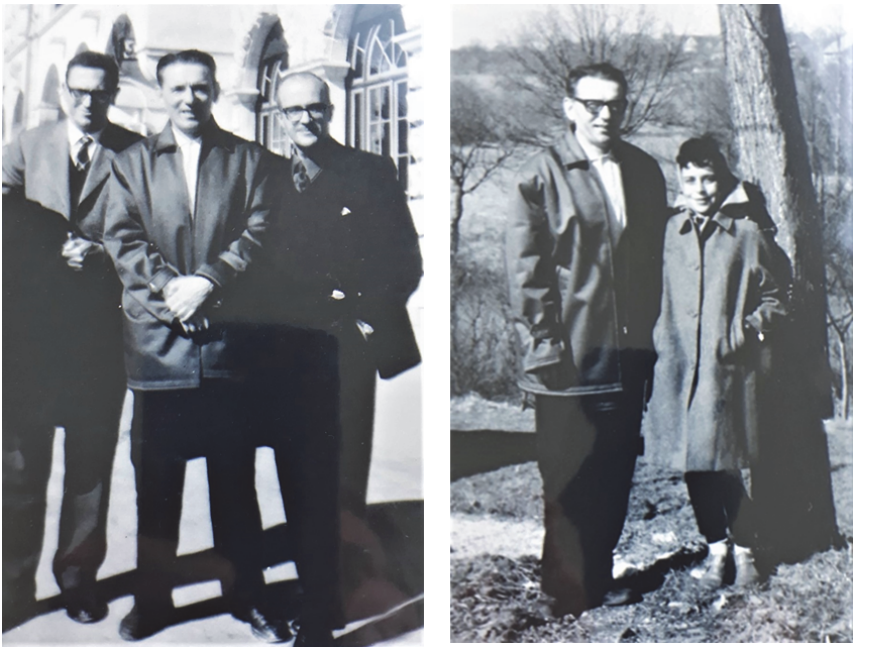

Fig. 7. (a) J.J. Giambiagi, J. Tiomno, C.G. Bollini, ICTP 1966. (b) Jayme Tiomno and Elisa Frota-Pessôa, ICTP 1966.

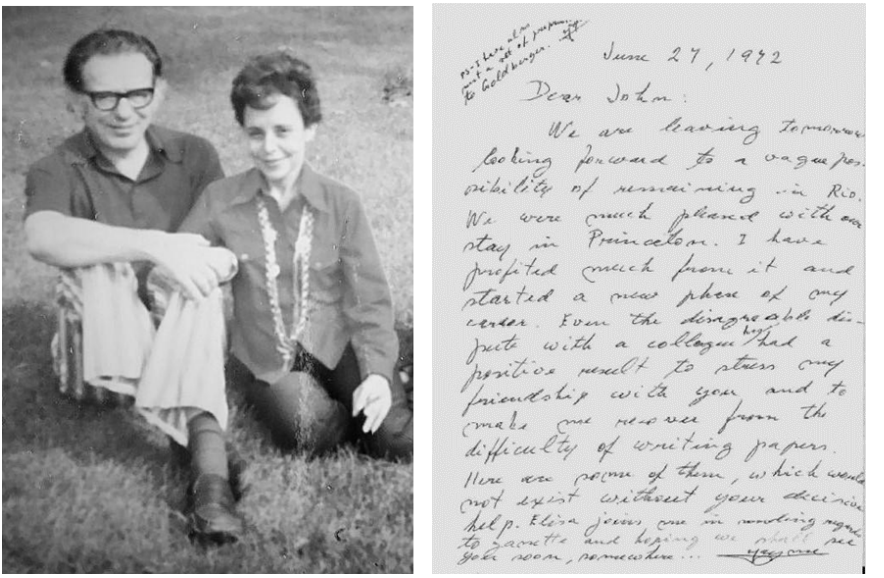
without your decisive help. Elisa joins me in sending regards to Janette and hoping we shall see you soon, somewhere . . . Jayme. PS. I have also sent a set of preprints to Goldberger."

We can only speculate on the precise details of the 'dispute' mentioned; it was probably a conflict over the publication of an article written jointly by Breuer, Ruffini, Tiomno and Vishveshwara (which appeared later in Phys. Rev. D. See Ref. 1 for more details).

After returning to Brazil in mid-1972, Jayme and Elisa were confronted with their continued blacklisting by the military dictatorship, which considered them to be 'subversive' (a charge which verges on the ridiculous, in retrospect). They could not even work at the private foundation CBPF, which they had helped to found and establish. Finally (after a Papal dispensation), they were given the opportunity to work at the Catholic University (PUC) in Rio de Janeiro, albeit with limited privileges. They remained there until after the Amnesty in 1979, and then still refused to beg for reinstatement to their university positions. Jayme finally rejoined the 'reformed' CBPF at the end of 1980; it was now an independent laboratory of the national science research funding agency CNPq. There, he became an honored and very active member of the faculty, retiring as 'Researcher emeritus' in 1992. For more information on the development of relativity and gravitation research after their 'rennaissance' in the 1950's, see the references.[3–5]



June 27, 1972

Dear John:

We are leaving tomorrow looking forward to a vague possibility of remaining in Rio. We were much pleased with our stay in Princeton. I have profited much from it and started a new phase of my career. Even the disagreeable dispute with a colleague had a positive result to strain my friendship with you and to make me recover from the difficulty of writing papers. Here are some of them, which would not exist without your decisive help. Elisa joins me in sending regards to Jeanette and hoping we shall see you soon, somewhere ... Yours

3. Tiomno's Scientific Work

Like Wheeler's scientific career, Tiomno's lifework can be divided into three distinct periods, although not so sharply:

– The first was his early work on relativity and particle physics, which extended from 1947 through about 1967. Highlights of this period were his work on the Weak Interaction (initially called the 'Universal Fermi Interaction', a term coined by Tiomno and C.N. Yang in 1949); his work on S-matrix theory and causality (with Walter Schützer; see Fig. 5); his prediction of the K* meson (with N. Zagury and A.L.L. Videira); and work on hyperons and global symmetry (with Abdus Salam).
– The second period began in the late 1960's and extended to around 1981. It was characterized by a shift in interest toward field theory, gravitation and cosmology, and was stimulated by collaborations with Giambiagi and Bollini as well as with his Princeton colleagues in 1971/72.
– The third period might be called his "eclectic phase", after he had returned to the CBPF in 1980, when he was involved in numerous projects relating to particle physics, Special Relativity, General Relativity, field theory, gravitation and cosmology, ending with his interest in relativistic rotating systems in the mid-1990's.

In the following, we give some selected examples of Tiomno's publications from the 1970's to the mid-1980's, as an illustration of the variety and the relevance of his work in his second and third periods.

3.1. *Some Selected Publications, 1970-1985*

(1) 'A Linear Theory of Gravitation', in: Lettere al Nuovo Cimento **3**, 65 (1970) (with C.G. Bollini and J.J. Giambiagi).
(2) 'Equivalence of Lorentz Transformations and Foldy-Wouthuysen Transformation for Free Spinor Fields', in: Physica **53**, 581–601 (1971).
(3) 'Electromagnetic Field of a Particle Moving in a Spherically-Symmetric Black-Hole Background', in: Lettere al Nuovo Cimento **3**, 211 (1972) (with R. Ruffini and C.V. Vishveshwara).
(4) 'Can Synchrotron Gravitational Radiation Exist?', in: Physical Review Letters **28**, 1352 (1972) (with Marc Davis, R. Ruffini and F. Zerilli).
(5) 'Pulses of Gravitational Radiation of a Particle Falling Radially into a Schwarzschild Black Hole', in: the Physical Review **D5**, 2932 (1972) (with Marc Davis and R. Ruffini).
(6) 'Maxwell Equations in a Spherically Symmetric Black-Hole Background', in: Lettere al Nuovo Cimento **5**, 851–855 (1972).
(7) 'Pair-Producing Electric Fields and Pulsars', in: the Astrophysical Journal **178**, 809 (1972) (with L. Parker).
(8) 'Polarization of Gravitational Synchrotron Radiation', in: Lettere al Nuovo Cimento **4**, 857 (1972) (with R.A. Breuer and C.V. Vishveshwara).
(9) 'Balancing of Electromagnetic and Gravitational Forces and Torque Between Spinning Particles at Rest', in: the Physical Review **D7**, 356 (1973).
(10) 'Gyromagnetic Ratio of a Massive Body', in: the Physical Review **D7**, 998 (1973) (with J.M. Cohen and R.M. Wald).
(11) 'Electromagnetic Field of Rotating Charged Bodies', in: the Physical Review **D7**, 992 (1973).
(12) 'Charged point particles with magnetic moments in General Relativity', in: Revista Brasileira de Física **8**, 350 (1978) (with Ricardo M. Amorim).
(13) 'On the relation between fields and potentials in non-abelian gauge fields', in: Revista Brasileira de Física **9**, 1 (1979) (with J.J. Giambiagi and C.G. Bollini).
(14) 'Singular potentials and analytic regularizations in classical Yang-Mills Equations', in: Journal of Math. Phys. **20**, 1967 (1979) (with C.G. Bollini and J.J. Giambiagi).
(15) 'Gauge field copies', in: Phys. Letters **83B**, 185 (1979) (with J.J. Giambiagi and C.G. Bollini).
(16) 'Wilson Loops and Related Strings for the instanton and its variational derivatives', in: Il Nuovo Cimento **59**, 412 (1980) (with C.G. Bollini and J.J. Giambiagi).
(17) 'Wilson Loops in Kerr Gravitation', in: Letters to Il Nuovo Cimento **81**, 13 (1981) (with C.G. Bollini and J.J. Giambiagi).
(18) 'Geodesic Motion and Confinement in Gödel's Universe', in: the Physical Review **D27**, 779 (1983) (with M. Novello and I.D. Soares).

(19) 'Gödel-type metric in Einstein-Cartan Spaces', in: Contributed Papers to the 10th International Conference on General Relativity and Gravitation, p. 507 (1983) (with A. Teixeira and J. Duarte).
(20) 'Homogeneity of Riemannian Spacetimes of Gödel type', in: the Physical Review **D28**, 1251 (1983) (with M. Rebouças).
(21) 'Pseudoscalar Mesons and Scalar diquarks—decay constants', in: Il Nuovo Cimento **81A**, 485 (1984) (with I. Bediaga, E. Predazzi, A.F.S. Santoro and M.H.G. Souza).
(22) 'Gravitational coupling of scalar and fermionic fields to matter vorticity: Microscopic asymmetries', in: Revista Brasileira de Física, Suppl. **14**, 372 (1984) (with I.D. Soares).
(23) 'Lifetimes in a quark-diquark system', in: Lettere al Nuovo Cimento **42**, 92–96 (1985) (with A.F.S. Santoro, I. Bediaga, M.G.H. Souza and E. Predazzi).
(24) 'On Experiments to detect possible failures of Relativity Theory', in: Foundations of Physics **15**, No. 9, pp. 945–961 (1985) (with W. Rodrigues).
(25) 'Gluon and qq mixing: [1440] system', in: Zeitschrift f. Physik **C30**, 493 (1985) (with A.C.B. Antunes, F. Caruso and E. Predazzi).
(26) 'Experiments to Detect Possible Weak Violations of Special Relativity', in: Physical Review Letters **55**, 143 (1985) (with A.K.A. Maciel).

Of special note are the publications that Tiomno himself listed as particularly important when he was nominated in 1995 for the Physics Prize of the Third-World Academy of Sciences (TWAS - an organization founded by Abdus Salam to complement the work of the ICTP). These include Items 1, 4, 9, 14, 16, 19, and 26 in the above list – and they illustrate how his interest in gravitation and field theory developed over the years.

4. ICRA and the MG Meetings. MG-X

The first international conference series to be initiated for the newly-revived field of General Relativity and Gravitation carried exactly that name – GR-1 was held at Chapel Hill, NC/USA in January 1957. It was organized by Bryce and Cécile (Morette) DeWitt, who had obtained positions at the University of North Carolina. In fact, it had a predecessor, a conference organized in Bern, Switzerland and held in July 1955 to celebrate the 50th anniversary of the initial publication of (Special) Relativity theory. It is often called 'GR-0', while later conferences in the series are listed as 'GR-1' etc. GR-2 took place in a former palace in Royaumont, near Paris, a location that was suggested by Cécile Morette DeWitt. Tiomno attended it, since he was in Europe at the end of his sabbatical year in London, 1958/59. This conference series continues today, now at three-year intervals, and GR-23 is scheduled for July 2022 in Beijing. Figure 9 shows Tiomno and Elisa in Paris in June 1959, at the end of their London stay, when he attended the Royaumont conference (GR-2). Tiomno also later published a paper in the proceedings of GR-10 (Item 19 in the above list).

Fig. 9. Jayme Tiomno and Elisa Frota-Pessôa in Paris, June 1959 (at the west end of the *Pont d'Iena*).

Another conference series was started in Dallas, TX/USA in 1963. It is called the 'Texas Symposia on Relativistic Astrophysics', and its initial motivation was to consider the newly-discovered Quasars in the light of relativity theory. This was the first time that the term 'Relativistic Astrophysics' was used publicly. An amusing account of the genesis of these conferences, which continue today at (usually) two-year intervals (the 31st is planned for December 2021 in Prague), was given by Engelbert L. Schucking, one of the original organizers from 1963, in *Physics Today* (August 1989, pp. 46-52).

In 1975, two of Tiomno's former collaborators, Abdus Salam and Remo Ruffini, founded the conference series 'Marcel Grossmann Meetings (on Recent Developments in Theoretical and Experimental General Relativity, Gravitation, and Relativistic Field Theories)', which should be familiar to the audience of this talk. Ruffini was at the time still officially at the Institute for Advanced Study in Princeton, but was on leave in 1975 as a visitor to the University of Western Australia (Nedlands)

and the University of Kyoto in Japan. The following year, he accepted a faculty position at the University of Catania, Sicily. Abdus Salam had been Head of the Department of Theoretical Physics at Imperial College London since 1957 (where Tiomno was one of the first visiting scientists, in the academic year 1958/59), and he became Director of the ICTP Trieste after its founding in 1964. The Centre offered a good platform for hosting the MG conferences, and the first two were held there in 1975 and 1979. MG-III, held in Shanghai in 1982, established the three-year interval still continued today. It was the result of the friendship between Remo Ruffini, who became Professor of Physics at his *alma mater*, the University of Rome 'La Sapienza' in 1978, and a Chinese visitor, Fang Li Zhi, whom he hosted in the late 1970's (cf. MG-XVI Awards Ceremony, Part 2). Later conferences in the series have been held in many cities on most of the continents.

Given his association with their founders and his own work in field theory, gravitation and cosmology, it was natural that Jayme Tiomno would have an interest in those meetings. But Tiomno, in spite of his close connection with the two founders of the MG conference series, did not attend the earlier MG meetings, both in Trieste; they took place during the 'leaden years' in Brazil, when he may not have been free to travel, and he had also not done any new, relevant research since leaving Princeton in 1972. By the time of MG-III, held in Shanghai/China in 1982, Remo Ruffini invited Mario Novello, from Tiomno's DRP Department at the CBPF, to participate in the meeting. Tiomno himself did not however attend the MG-III meeting; it was far from Brazil and perhaps difficult for him to obtain a visa.

Fig. 10. (a) Tiomno, Elisa and Mario Novello, 1991. (b) Tiomno with his last collaborator, Ivano Soares, in 1997.

In 1985, Ruffini and Abdus Salam, together with several other prominent scientists, founded the ICRA organization (International Center for Relativistic Astrophysics), based in Rome and Pescara, Italy (ICRANet). By 1985, Tiomno's time

had come, and he gave an invited paper on the LET–SRT controversy at MG-IV, held that year for the first time in Rome. Remo Ruffini and Abdus Salam were no doubt pleased to give him the opportunity to experience an MG conference, and Novello's enthusiasm also played an important role in convincing him to attend. After the meeting in Rome, Tiomno resumed his contacts with his former collaborators, and in 1994, the year of MG-VII, held in Stanford/CA, USA, he was a member of the 'Committee of the Americas', part of the international coordinating committee for the conference; but he again did not attend the meeting itself—by then, as *researcher emeritus*, he was reducing his overseas travel and participation in conferences, and encouraging some of his former students and collaborators to actively take over those functions, including Mario Novello and Marcelo Rebouças, among others.

Prior to the MG-X Meeting planned for 2003, the Brazilian physicists offered to host the conference at the CBPF, and Mario Novello served as chairman of its local organizing committee. At that meeting, the Institutional Award, presented at each conference to an outstanding institution in research and teaching, was given to the CBPF 'for its role as a teaching and research institution and as a place originating fundamental physics ideas in the exploration of the universe', and presented to its founders, César Lattes, José Leite Lopes, and Jayme Tiomno, who were all present.

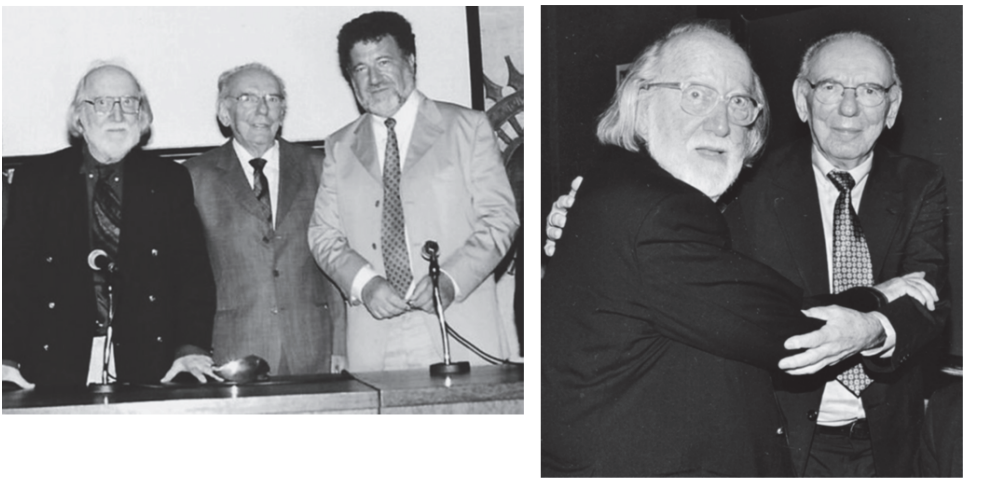

Fig. 11. (a) José Leite Lopes, Tiomno, and Remo Ruffini at the prize ceremony, MG-X, 2003. (b) Leite Lopes and Tiomno at MG-X in Rio, 2003.

That same year, ICRANet, the international networking arm of ICRA, was officially chartered. Ruffini needed at least three states to create it, and at the time, he had just two: the Vatican and Armenia. Brazil's membership in ICRANet was

also prepared at the 2003 Meeting, and Mario Novello later became its representative for Brazil (a post now occupied by Ulisses Barres de Almeida of the CBPF). Brazil formally agreed to join in 2005, and its membership was finalized in 2011.

Thus, although Jayme Tiomno himself was not strongly engaged in these meetings, his influence continues to be felt in them through the *Centro* that he helped to found, and through his former students and collaborators, who are actively involved in them, both scientifically and organizationally.

5. Conclusions

The three major strands of fundamental physics in the 20th century have wound their way through the decades, producing many offshoots and sometimes seeming to fuse into a single strand. They each experienced periods of hectic activity and rapid progress, and longer periods of relative neglect and apparent stagnation.

Particle physics reached its preliminary climax in the late 1970's with the formulation of the Standard Model of Particle Physics (combining the electroweak unified theory with quantum chromodynamics to describe three of the four fundamental interactions (weak, strong, electromagnetic); however leaving gravity out of the picture). In the intervening 40 years, the SMPP has been completed and perfected, but although no one really believes it to be the 'last word' on the microscopic world, the predicted 'new physics' beyond the SMPP has failed to appear, both experimentally and theoretically.

Gravitational physics has also produced the Standard Model of Cosmology (based on GR), and it has been enriched by many new discoveries and technical advances. But the SMC leaves many open questions and unsolved problems: dark matter, dark energy, inflation; and its fundamental constant, the Hubble constant, is currently the subject of conflicting measured values.

Fundamental quantum mechanics has given rise to a number of important offshoots: quantum optics, quantum information, quantum computing; but the interpretation of quantum mechanics is still elusive, as is its combination with gravity – quantum gravity.

Jayme Tiomno contributed significantly to all three of those major strands. But also, and for him more importantly, he contributed to the establishment and improvement of physics education and research in his native country, Brazil. This was his most serious goal during his long lifetime, and he made major contributions to its present success. The lesson to be learned from his lifelong efforts is that serious and honest work often leads to unexpected and lasting successes, even though it faces drastic obstacles and may appear hopeless at the time.

Acknowledgments

The author thanks Prof. Alfredo Tiomno Tolmasquim for much effort in the preparation of our joint book, reference,[2] upon which much of this article is based. Readers should consult it for many more references to original sources. Thanks are due also to Prof. Luis Carlos Bassalo Crispino, who was chairman of the session of MG-XVI where this paper was presented.

In this contribution we report about Feynman's approach to gravitation, starting from the records of his interventions at the Chapel Hill Conference of 1957. As well known, Feynman was concerned about the relation of gravitation with the rest of physics. Probably for this reason, he promoted an unusual, field theoretical approach to general relativity, in which, after the recognition that the interaction must be mediated by the quanta of a massless spin-2 field, Einstein's field equations should follow from the general properties of Lorentz-invariant quantum field theory, plus self-consistency requirements. Quantum corrections would then be included by considering loop diagrams. These ideas were further developed by Feynman in his famous lectures on gravitation, delivered at Caltech in 1962-63, and in a handful of published papers, where he also introduced some field theoretical tools which were soon recognized to be of general interest, such as ghosts and the tree theorem. Some original pieces of Feynman's work on gravity are also present in a set of unpublished lectures delivered at Hughes Aircraft Company in 1966-67 and devoted primarily to astrophysics and cosmology. Some comments on the relation between Feynman's approach to gravity and his ideas on the quantum foundations of the fundamental interactions are included.

Keywords: Gravitation; Quantum field theory; Loop diagrams.

1. Introduction: A timeline

Among the many scientific interests that Feynman had in the 1950s and in the 1960s, a prominent place was taken by the understanding of the relation of gravitation to the rest of physics,[a] and in particular the assessment of its consistency with the uncertainty principle.[b] Feynman likely began to seriously think about gravity in

[a] "Next we shall discuss the possible relation of gravitation to other forces. There is no explanation of gravitation in terms of other forces at the present time. It is not an aspect of electricity or anything like that, so we have no explanation. However, gravitation and other forces are very similar, and it is interesting to note analogies." (Ref. 1, Vol. 1, Sec. 7-7); "My subject is the quantum theory of gravitation. My interest in it is primarily in the relation of one part of nature to another." (Ref. 2, p. 697).

[b] "...it would be important to see whether Newton's law modified to Einstein's law can be further modified to be consistent with the uncertainty principle. This last modification has not yet been completed." (Ref. 1, Vol. 1, Sec. 7-8).

the early 1950s, just after completing his work on quantum electrodynamics. This was attested by Murray Gell-Mann[3] in a paper written for a Physics Today special issue devoted to Feynman's legacy,[c] as well as by Bryce S. DeWitt,[4] in a letter to Agnew Bahnson written in November 1955.[5] Feynman's efforts began in a period in which general relativity, after a stagnation which lasted about thirty years, was gradually emerging as a mainstream research area, giving rise to a process known as the *renaissance* of general relativity.[6]

A crucial event to consider, in order to reconstruct Feynman's approach to gravitation, is the 1957 Chapel Hill conference[4] on *The Role of Gravitation in Physics*, which was also pivotal to the renaissance of general relativity. At that conference, the gravitational physics community delineated the tracks along which subsequent work would develop in the subsequent decades. The main threads were the following[7]: classical gravity, quantum gravity, and the classical and quantum theory of measurement (as a bridge between the previous two topics). In that conference Feynman's work on gravity, of which nothing had been published yet, was presented for the first time, and put on paper in the records.[4] In fact these written records testify that by the time of the conference he had already deeply thought, and performed computations, about each of the above listed three topics, focusing in particular on classical gravitational waves, on the arguments in favor of quantum gravity from fundamental quantum mechanics, and finally on quantum gravity itself. Thus, in this contribution, we take as starting point for our reconstruction Feynman's interventions at Chapel Hill and follow the development of his work in the subsequent years, until the late sixties, where he apparently lost interest in the subject.

The ultimate goal of Feynman's work was the development of a quantum field theory of gravitation, which led him to face deep conceptual as well as mathematical issues, such as divergent integrals and the lack of unitarity beyond the tree level approximation. This task accompanied Feynman for some years, as stated in a letter[8] he wrote to Viktor F. Weisskopf in 1961 ("As you know, I am studying the problem of quantization of Einstein's General Relativity. I am still working out the details of handling divergent integrals which arise in problems in which some virtual momentum must be integrated over"), as well as reported by William R. Frazer[9] in a short summary of the talks given at the La Jolla conference, later in the same year.[d] A first comprehensive account of Feynman's results on quantum gravity can

[c]Indeed here Gell-Mann remembered his visit to Caltech during the Christmas vacation of 1954-55, the discussions with Feynman about quantum gravity, and the fact that Feynman "had made considerable progress".

[d]The International Conference on the Theory of Weak and Strong Interactions was held in June 14-16, 1961, at the University of California, San Diego, in La Jolla. Here, Geoffrey F. Chew gave his celebrated talk on the S-matrix,[10] while an afternoon session was devoted to the theory of gravitation, where Feynman reported on his work on the renormalization of the gravitational field, and recognized non-unitarity as the main difficulty, which was shared also by Yang-Mills theory.

be found in the talk he gave in 1962 at the Warsaw conference,[e] whose written version was later published as a regular paper in Acta Physica Polonica.[2] Further details were given by Feynman much later, in a couple of papers[11,12] published in 1972 in the Festschrift for John A. Wheeler's 60th birthday,[13] which were written in a period in which he was already deeply absorbed in the study of partons and strong interactions.

Among the main sources which contribute to offer a clear account of Feynman's work on gravity issues, it is mandatory to include the famous Caltech Lectures on Gravitation,[14] delivered in 1962-63 and aimed to advanced graduate students and postdocs. Finally, there is some unpublished material, included in two sets of lectures, given in the 1960s at the Hughes Aircraft Company, which only recently have been made available on the web.[f] In particular, the 1966-67 set of lectures,[16] which were devoted to astronomy, astrophysics and cosmology, contains an introductory treatment of general relativity, with an emphasis on applications to the main subjects. While sharing many similarities with the above quoted Caltech lectures,[14] the Hughes treatment offers to the attentive reader several original points. In those same years Feynman had succeeded in finding a new derivation of Maxwell's equations,[17,18] and a generalization of this approach to gravity is suggested (but not pursued) in several places in the Hughes lectures on astrophysics, as well as in the set of lectures given in the following year and devoted to electromagnetism.[19]

After outlining the main steps and sources which helped us to reconstruct the full development of Feynman's work on gravitation,[g] in this contribution we focus on two key issues: the formulation of quantum gravity as a quantum field theory of a massless spin-2 field, the graviton, in whole analogy with quantum electrodynamics, which is the content of Section 2, and the unitarity and renormalization issues arising beyond the tree level approximation, presented in Section 3. Our concluding remarks close the paper.

2. Gravity as a quantum field theory

Feynman's strategy in approaching gravity was firstly outlined at Chapel Hill conference in a series of critical comments (Ref. 4, pp. 272-276), in which a non-geometric and field theoretical line of attack is put forward. His starting point was an hypothetical, counterfactual situation, in which scientists would discover the principles of Lorentzian quantum field theories before general relativity.[h] The main concern in

[e]The International Conference on General Relativity and Gravitation was held in Jabłonna and Warsaw in July 25-31, 1962, with Leopold Infeld as the chairman of the local organizing committee. The discussion focused on three main topics: the general properties of gravitational radiation, the quantization of gravity and the exact solutions of the Einstein field equations.

[f]See Ref. 15 for a brief account of Feynman's involvement in teaching at the Hughes Aircraft Company.

[g]See Ref. 20 for a comprehensive account of this work.

[h]In fact, in Ref. 4, p. 273, Feynman said: "Instead of trying to explain the rest of physics in terms of gravity I propose to reverse the problem by changing history. Suppose Einstein never existed [...]".

such a situation would then be to include a new force, the gravitational one, in the framework of quantum field theory. This approach would be later completed in the first part of the Caltech lectures.[14] Feynman's reasoning was the following: on the basis of the general principles of quantum field theory and of experimental results it is possible to conclude that gravity, as any other force, has to be mediated by exchanges of a virtual particle, which in this case is a massless neutral spin-2 quantum, the graviton. Thus, by constructing a Lorentz invariant quantum field theory of the graviton[i] and by imposing certain consistency requirements, full general relativity should be recovered. Clearly, by following the same procedure for the spin-1 case Maxwell's equations are obtained (in this case it is much simpler, being the theory linear). Such an approach testifies his ideas about fundamental interactions as manifestations of underlying quantum theories,[18] which were expressed by him several times, for example in the Hughes Lectures[19]:

> I shall call conservative forces, those forces which can be deduced from quantum mechanics in the classical limit. As you know, Q.M. is the underpinning of Nature (Ref. 19, p. 35).

Let us describe the steps in more detail. First of all, one has to establish the spin of the mediating quantum. Both in the Caltech[14] and in the 1966-67 Hughes lectures,[16] the choice of a spin-2 mediator was justified by the observation that energy, which is the source of the gravitational force, grows with the velocity. The same observation ruled out the possibility of a spin-0 field, because the associated charge would decrease with the velocity. This result can be traced back to an old argument by Einstein (never published but recalled in Ref. 26, pp. 285-290), according to which the vertical acceleration of a body would depend on its horizontal velocity, and in particular would be zero for light, making light deflection impossible. Once the spin of the graviton is established, one can easily construct the linearized theory of the associated field, which is a massless spin-2 field. Nonlinearity then comes into play because the graviton has to couple with anything carrying energy-momentum, then also with itself, and this coupling must be universal. The resulting nonlinear theory is general relativity. General covariance and the geometric interpretation of general relativity are finally recovered as a byproduct of the gauge invariance of the theory[j]. For Feynman, this was only half of the whole story. In fact, by pushing calculations beyond tree level, quantum gravity effects would be taken into account. This was Feynman's ultimate goal, i.e. obtaining a quantum theory of gravity, which in this approach amounts to the quantization of another field.

---

[i]The linear theory for a massless spin-2 field and its massive counterpart was completely worked out by Markus Fierz and Wolfgang E. Pauli in Ref. 21, on the basis of a previous work by Paul A. M. Dirac,[22] while iterative arguments similar to Feynman's ones were later put forward by Suraj N. Gupta[23] and Robert H. Kraichnan[24] in an attempt to generate infinite nonlinear terms both in the Lagrangian and in the stress-energy tensor. See for details Ref. 25.

[j]See Ref. 14, p. 113.

Let us describe how Feynman sketched the above procedure at the Chapel Hill conference (Ref. 4, pp. 272-276). In whole analogy with electrodynamics, he wrote down the following action:

$$\int \left(\frac{\partial A_\mu}{\partial x_\nu} - \frac{\partial A^\nu}{\partial x^\mu}\right)^2 \mathrm{d}^4x + \int A_\mu j^\mu \mathrm{d}^4x + \frac{m}{2}\int \dot{z}_\mu^2 \mathrm{d}s + \frac{1}{2}\int T_{\mu\nu}h^{\mu\nu}\mathrm{d}^4x + \int (\text{second power of first derivatives of } h), \qquad (1)$$

where $h_{\mu\nu}$ is the new field associated with the graviton, i.e. a symmetric second-order tensor field, which satisfies second order linear equations of the kind:

$$h^{\mu\nu,\sigma}{}_{,\sigma} - 2\overline{h}^{\mu}{}_{\sigma}{}^{,\nu\sigma} = \overline{T}^{\mu\nu}, \qquad (2)$$

where the *bar* operation is defined on a generic second rank tensor $X_{\mu\nu}$ as:

$$\overline{X}_{\mu\nu} = \frac{1}{2}\left(X_{\mu\nu} + X_{\nu\mu}\right) - \frac{1}{2}\eta_{\mu\nu}X^\sigma{}_\sigma. \qquad (3)$$

The equations of motion for particles also follow from the above action:

$$g_{\mu\nu}\ddot{z}^\nu = -\left[\rho\sigma,\mu\right]\dot{z}^\rho\dot{z}^\sigma, \qquad (4)$$

where $g_{\mu\nu} = \eta_{\mu\nu} + h_{\mu\nu}$, $\eta_{\mu\nu}$ is the Minkowski metric, and $[\rho\sigma,\mu]$ are the Christoffel symbols of the first kind.

However, when the field $h_{\mu\nu}$ is coupled to the matter according to Eq. (4), the corresponding stress energy tensor $T_{\mu\nu}$ does *not* obey to a conservation law, leading to a consistency problem. This happens at variance with electromagnetism, where Maxwell equations guarantee conservation of the current j^μ. Instead here $T_{\mu\nu}$ does not take into account the effect of gravity on itself, which requires nonlinearity.[k] Thus a suitable $T_{\mu\nu}$ has to be found in order to satisfy the condition $\partial_\nu T^{\mu\nu} = 0$. The solution to this consistency issue[l] can be obtained by adding to the action a nonlinear third order term in $h_{\mu\nu}$, which leads to the following equation for $T_{\mu\nu}$:

$$g_{\mu\lambda}T^{\mu\nu}{}_{,\nu} = -\left[\rho\nu,\lambda\right]T^{\rho\nu}. \qquad (5)$$

One can then go on to higher order approximations, until the procedure converges. But finding the general solution of Eq. (5) is a really difficult task in the absence of a standard procedure. Feynman's idea was to look for an expression for the $T_{\mu\nu}$, and hence for the action, that is invariant under the following infinitesimal transformation of the whole tensor field $g_{\mu\nu}$:

$$g'_{\mu\nu} = g_{\mu\nu} + g_{\mu\lambda}\frac{\partial A^\lambda}{\partial x^\nu} + g_{\nu\lambda}\frac{\partial A^\lambda}{\partial x^\mu} + A^\lambda\frac{\partial g_{\mu\nu}}{\partial x^\lambda}, \qquad (6)$$

where the 4-vector A^λ is the generator. This is a geometric transformation in a Riemannian manifold with metric, hence one can say that geometry gives the metric

[k] Feynman noticed that nonlinearity was necessary in order to explain the precession of the perihelion of Mercury (as discussed in Ref. 14, p. 75).

[l] See for details Refs. 4, p. 274 and 14, pp. 78-79.

$g_{\mu\nu}$. As such, in Feynman's approach geometry comes into play at the end and not at the beginning. By working out calculations, the full nonlinear Einstein gravitational field equations are obtained.

Lectures 3-6 of Feynman's graduate course on gravitation (Ref. 14) contain all the details of the above procedure. Interestingly, a proof is also given of the ability of this field theory based formalism to reproduce key physical effects of curved spacetime geometry. For instance, in Lecture 5 (Ref. 14, pp. 66-69) it is shown that, in the action of a scalar field, the time dilation $t \to t' = t\sqrt{1+\epsilon}$ exactly reproduces the effect of a constant weak gravitational field described by the tensor $g_{44} = 1+\epsilon$, $g_{ii} = -1$, $i = 1, 2, 3$. Incidentally such an effect plays a pivotal role in producing the right result for the precession of Mercury's perihelion. Before moving to applications, Feynman devoted some lectures to the discussion of the usual geometric approach to gravity and of its link with the field theory based approach (Ref. 14, Lectures 7-10):

> Let us try to discuss what it is that we are learning in finding out that these various approaches give the same results (Ref. 14, p. 112).

Despite advocating one approach over another, Feynman was in fact intrigued by the double nature of gravity, which has both a geometrical interpretation and a field interpretation, and in Section 8.4 of Ref. 14 he recognized how an explanation may be provided by gauge invariance. Indeed a viable procedure may be established in order to obtain the invariance of the equations of physics under space dependent variable displacements. This amounts to looking for a more general Lagrangian, to be obtained by adding to the old one new terms, involving a gravity field. The net result is a new picture of gravity, as the field corresponding to a gauge invariance with respect to displacement transformations.

Summing up, Feynman succeeded in obtaining the full nonlinear Einstein equations by means of a consistency argument applied to a Lorentz invariant quantum field theory of the graviton. According to John Preskill and Kip S. Thorne,[25] it is likely that he was completely unaware of the earlier work by Gupta[23] and Kraichnan,[24] which as mentioned had been developed along a similar line of attack, but was still incomplete. So he would have developed his approach independently, besides getting more complete results. A Lorentz-invariant field theoretical approach to gravity would have been later pursued also by Steven Weinberg,[27,28] albeit quite different from Feynman's one,[m] as well as by Stanley Deser.[29–32] Indeed Deser's approach, while being similar to Feynman's one, was more elegant and general and led to completion the whole program started with Kraichnan and Gupta. Finally, a rigorous and general analysis of the relation between spin-2 theories and general covariance was carried out by Robert M. Wald.[33]

[m] Weinberg's approach relied on the analyticity properties of graviton-graviton scattering amplitudes, and it was quite more general, since Weinberg actually proved that a quantum theory of a massless spin-2 field can only be consistent if this field universally couples to the energy-momentum of matter, hence the equivalence principle has to be obeyed.

3. Fighting with loops: The renormalization of gravity

After obtaining the Einstein-Hilbert action and the full nonlinear Einstein gravitational field equations, Feynman's efforts were mainly directed towards discussing quantum field theory issues beyond the tree level approximation, i.e. loop diagrams, unitarity and renormalization.

To the best of our knowledge, these issues were publicly addressed for the first time by Feynman in 1961 at the already mentioned La Jolla conference,[9] where nonlinearity was recognized as the very source of difficulty within both gravitation and Yang-Mills theories. Indeed the sources of the gravitational field are energy and momentum, and the gravitational field carries energy and momentum itself. In the same way, the source of a Yang-Mills field is the isotopic spin current, and the Yang-Mills field carries isotopic spin itself. This means that both the gravitational field and the Yang-Mills field are self-coupled, resulting in nonlinear field theories. A difficulty that nonlinearity brings about is the fact that loop diagrams seem to clash with unitarity.

As recalled in the introduction, Feynman's results on quantum gravity can be found in a report of the talk given at the 1962 Warsaw conference, later published in Acta Physica Polonica,[2n] with many details discussed much later in the two 1972 Wheeler Festschrift papers.[11,12]

Also in this case Feynman followed his original strategy, leaving aside quantization of space-time geometry, constructing a quantum field theory for the graviton, and working out results at different perturbative orders. Since the goal was the quantum theory, the Einstein equations and the corresponding Lagrangian were assumed as a starting point, rather than derived from scratch. The theory was coupled to a scalar field, and perturbative calculations up to the next to leading order were pursued. This implied the inclusion of loop diagrams, which make quantum corrections to enter the game. In Feynman's own words:

> I started with the Lagrangian of Einstein for the interacting field of gravity and I had to make some definition for the matter since I'm dealing with real bodies and make up my mind what the matter was made of; and then later I would check whether the results that I have depend on the specific choice or they are more powerful (Ref. 2, p. 698).

The metric was split in the following way:

$$g_{\mu\nu} = \delta_{\mu\nu} + \kappa h_{\mu\nu}; \tag{7}$$

where the Minkowski metric is here denoted by $\delta_{\mu\nu}$ and κ is a dimensionful coupling constant. Substituting (7) and expanding, the Lagrangian for gravity coupled with

[n] As pointed out by Trautman in some recently published memories (34, p. 406), the text of Feynman's plenary lecture became available too late to be included in the proceedings, therefore it was published only in 1963 as a regular paper.

a scalar field can be cast in the form:

$$L = \int \left(h_{\mu\nu,\sigma}\overline{h}_{\mu\nu,\sigma} - 2\overline{h}_{\mu\sigma,\sigma}\overline{h}_{\mu\sigma,\sigma}\right) \mathrm{d}\tau + \frac{1}{2}\int \left(\phi_{,\mu}^2 - m^2\phi^2\right) \mathrm{d}\tau \tag{8}$$
$$+ \kappa \int \left(\overline{h}_{\mu\nu}\phi_{,\mu}\phi_{,\nu} - m^2\frac{1}{2}h_{\sigma\sigma}\phi^2\right) \mathrm{d}\tau + \kappa \int (hhh)\, \mathrm{d}\tau + \kappa^2 \int (hh\phi\phi)\, \mathrm{d}\tau + ...$$

where the bar operation has been defined in (3) and a schematic notation has been adopted for the highly complex higher order terms. The first two terms are simply the free Lagrangians of the gravitational field and of matter, respectively. Before considering radiative corrections the classical solution of the problem was worked out, which involved the variation of Eq. (8) with respect to h and, then, to ϕ, giving rise to the following equations of motion with a source term:

$$h_{\mu\nu,\sigma\sigma} - \overline{h}_{\sigma\nu,\sigma\mu} - \overline{h}_{\sigma\mu,\sigma\nu} = \overline{S}_{\mu\nu}\,(h,\phi)\,, \tag{9}$$
$$\phi_{,\sigma\sigma} - m^2\phi = \chi\,(\phi,h)\,. \tag{10}$$

A close inspection revealed that Eq. (9) was singular, so that Feynman was forced to resort to the invariance of the Lagrangian under the transformation:

$$h'_{\mu\nu} = h_{\mu\nu} + 2\xi_{\mu,\nu} + 2h_{\mu\sigma}\xi_{\sigma,\nu} + \xi_\sigma h_{\mu\nu,\sigma}, \tag{11}$$

ξ_μ being arbitrary. This meant that the source $S_{\mu\nu}$ had to be divergenceless in order to make Eq. (9) consistent. Finally, by making the gauge choice $\overline{h}_{\mu\sigma,\sigma} = 0$, the law of the gravitational interaction of two systems by means of the exchange of a virtual graviton was obtained. Feynman then went on computing other processes, such as an interaction vertex coupling two particles and a graviton and the gravitational analog of gravitational Compton effect (i.e. with a graviton replacing the photon).

After these preliminary calculations, Feynman went to the next to leading order approximation, thus encountering diagrams with closed loops:

> However the next step is to take situations in which we have what we call closed loops, or rings, or circuits, in which not all momenta of the problem are defined (Ref. 2, pp. 703-704).

He realized that working out closed loop diagrams required the solution of a number of conceptual issues, and he succeeded in showing that any diagram with closed loops can be expressed in terms of sums of on shell tree diagrams, which is the content of his celebrated tree theorem (which was treated in detail in Ref. 11). Further details on the statement of the tree theorem and, in particular, on the nature of the proof for the one-loop case were given by Feynman in the discussion section (Ref. 2, pp. 714-717), while answering some related questions by DeWitt. But the main problem to face in carrying out one-loop calculations was the lack of unitarity, due to the presence of contributions arising from the unphysical longitudinal polarization states of the graviton, which did not cancel as they should. Following a suggestion

by Gell-Mann,[o] Feynman considered the simpler Yang-Mills case (his results in this case were summarized in Ref. 12) and found the same pathological behavior:

> But this disease which I discovered here is a disease which exist in other theories. So at least there is one good thing: gravity isn't alone in this difficulty. This observation that Yang-Mills was also in trouble was of very great advantage to me. [...] the Yang-Mills theory is enormously easier to compute with than the gravity theory, and therefore I continued most of my investigations on the Yang-Mills theory, with the idea, if I ever cure that one, I'll turn around and cure the other (Ref. 2, p. 707).

The solution to this issue was obtained by expressing each loop diagram as a sum of trees and then computing the trees. This worked even if the process of opening a loop by cutting a graviton line implies the replacement of a virtual graviton with a real transverse one. Finally, in order to guarantee gauge invariance the sum of the whole set of tree diagrams corresponding to a given process has to be taken.

The same results, according to Feynman, could be obtained by direct integration of the closed loop. In the last case a mass-like term has to be added to the Lagrangian to avoid singularity but at the price of breaking gauge invariance. At the same time a contribution has to be subtracted, which is obtained by making a ghost particle (with spin-1 and Fermi statistics) to go around the loop and artificially coupled to the external field. In this way both unitarity and gauge invariance would be restored. This procedure was worked out also for Yang-Mills theory, but in that case the ghost particle has spin-0.[12]

Once successfully solved the one-loop case, Feynman's efforts pointed toward a further generalization of the above procedure to two or more loops:

> Now, the next question is, what happens when there are two or more loops? Since I only got this completely straightened out a week before I came here, I haven't had time to investigate the case of 2 or more loops to my own satisfaction. The preliminary investigations that I have made do not indicate that it's going to be possible so easily gather the things into the right barrels. It's surprising, I can't understand it; when you gather the trees into processes, there seems to be some loose trees, extra trees (Ref. 2, p. 710).

But, in Feynman's words, preliminary attempts seem to suggest that novel difficulties enter the game when dealing with two or more loops, as also mentioned in the last of his published Lectures on Gravitation (Ref. 14, Lecture 16, pp. 211-212). Here, once again, he recognized in the lack of unitarity of some sums of diagrams the main source of the observed pathological behavior and pointed out that a similar

[o] "I suggested that he try the analogous problem in Yang-Mills theory, a much simpler nonlinear gauge theory than Einsteinian gravitation." (Ref. 3, p. 53).

feature was shared also by Yang-Mills theory. Finally, while hinting at the problem of finding ghost rules for high order diagrams, he argued in favor of the non-renormalizability of gravity as a consequence of these difficulties:

> I do not know whether it will be possible to develop a cure for treating the multi-ring diagrams. I suspect not – in other words, I suspect that the theory is not renormalizable. Whether it is a truly significant objection to a theory, to say that it is not renormalizable, I don't know (Ref. 14, Lecture 16, pp. 211-212).

It is not clear whether Feynman was suggesting a link between non-unitarity and non-renormalizability issues. But in any case Feynman's results played a prominent role in the development of gauge theory and quantum gravity. Feynman's rules for ghosts were later generalized to all orders by DeWitt,[35–37] while Ludvig D. Faddeev and Viktor N. Popov[38] derived them in a much simpler way, by means of functional integral quantization, setting the standard for all subsequent work in the field. In particular, DeWitt proved that Yang-Mills theory and quantum gravity are in fact unitary at two[35] and arbitrarily many loops.[36,37] However, while Yang-Mills theory was later shown to be renormalizable (cf. Refs. 39-42), gravity presented divergences which could not be renormalized (cf. Refs. 43-46), confirming Feynman's suspect. It should be mentioned that, in subsequent years, modified theories of gravity, characterized by an action quadratic in the curvature, have been put forward. Unlike ordinary general relativity, these theories are renormalizable but not unitary.[47]

It is worth mentioning that, unlike most of his contemporaries, Feynman did not think about non-renormalizability as a signature of inconsistency of a theory, as also recalled by Gell-Mann,[p] and claimed by Feynman himself in one of his last interviews, given in January 1988:

> The fact that the theory has infinities never bothered me quite so much as it bother others, because I always thought that it just meant that we've gone too far: that when we go to very short distances the world is very different; geometry, or whatever it is, is different, and it's all very subtle (48, p. 507).

In fact, within the modern view on quantum field theory, which was developed in 1970s, non-renormalizability is considered only a signature of the fact that the theory loses its validity at energies higher that a certain scale. Nevertheless, one has an *effective field theory*, which works and can be useful to make predictions under that scale (interesting historical discussions can be found in Refs. 49 and 50). This is true also for gravity.[51] But, as remembered by John P. Preskill in a recent talk

[p] "He was always very suspicious of unrenormalizability as a criterion for rejecting theories" (Ref. 3, p. 53).

(Ref. 52, slide 37), although he anticipated this view, apparently Feynman was not really at ease with it:

> I spoke to Feynman a number of times about renormalization theory during the mid-80s (I arrived at Caltech in 1981 and he died in 1988). I was surprised on a few occasions how the effective field theory viewpoint did not come naturally to him". [...] Feynman briefly discusses in his lectures on gravitation (1962) why there are no higher derivative terms in the Einstein action, saying this is the "simplest" theory, not mentioning that higher derivative terms would be suppressed by more powers of the Planck length.

As a further remark, let us notice that in the last years Feynman's tree theorem has spurred a renewed interest in researchers working in the context of advanced perturbative calculations and generalized unitarity (cf. Refs. 53-57).

4. Concluding remarks

In this paper we focused on Feynman's contributions to the research in quantum gravity, starting from his interventions at Chapel Hill conference in 1957 and ending with the Wheeler festschrift papers. His approach was field theoretical rather than geometric, reflecting his strong belief in the unity of Nature, which is quantum at the deepest level. Quantization of gravity, according to him, simply had to be considered as the quantization of another field, the spin-2 graviton field. In this way full general relativity would be recovered at leading order, while the inclusion of loop diagrams brought into the picture a bunch of new difficulties. In this respect, Feynman's struggle against loops, while succeeding at one-loop order, failed with two- and higher-loop diagrams. Nevertheless, his results triggered further efforts and some tools he developed, such as the tree theorem, have recently become of widespread use among people working on scattering amplitudes.

An account of Richard Feynman's work on gravitational waves is given. Feynman's involvement with this subject can be traced back to 1957, when he attended the famous Chapel Hill conference on the Role of Gravitation in Physics. At that conference, he presented in particular the celebrated sticky bead argument, which was devised to intuitively argue that gravitational waves must carry energy, if they exist at all. While giving a simple argument in favor of the existence of gravitational waves, Feynman's thought experiment paved the way for their detection and stimulated subsequent efforts in building a practical detecting device. Feynman's contributions were systematically developed in a letter to Victor Weisskopf, completed in February 1961, as well as in his Caltech Lectures on Gravitation, delivered in 1962-63. There, a detailed calculation of the power radiated as gravitational radiation was performed, using both classical and quantum field theoretical tools, leading to a derivation of the quadrupole formula and its application to gravitational radiation by a binary star system. A comparison between the attitudes of Feynman and of the general relativity community to the problems of gravitational wave physics is drawn as well.

Keywords: History of physics; History of relativity; Gravitational waves.

1. Introduction

The contributions of Richard P. Feynman to physics notoriously touched all four fundamental interactions of Nature. His first breakthrough occurred in the theory of electromagnetism, with his version of covariant quantum electrodynamics that earned him the 1965 Nobel prize,[1] which was developed by him between the late 1940s and the early 1950s. A few years later, Feynman's interest had focused on another fundamental interaction, namely gravity. Feynman first mentioned this new interest of his to Murray Gell-Mann, who much later recalled:

> We first discussed it when I visited Caltech during the Christmas vacation of 1954-55 [...] I found that he had made considerable progress.[2]

In view of this statement,[a] it is conceivable that Feynman's interests were directed towards gravity some time before 1954, probably shortly after completing his work on quantum electrodynamics. While working also on other subjects, most notably condensed matter physics and the theory of weak interactions,[5] Feynman nurtured his interest in gravity at least until the second half of the 1960s. In these fifteen years, he gave several contributions to the both classical and quantum gravity, some of which would later be recognized as pivotal for the field. The first public contribution to gravity was given by Feynman at the Chapel Hill conference in 1957,[4] where he took active part to many of the numerous discussion sessions. After that, records of his later work are documented by several published and unpublished sources. For detailed historical accounts of Feynman's contributions to gravitational physics, see Refs. 6 and 8.

In this paper, we focus on Feynman's work on gravitational waves. As well-known, at Chapel Hill Feynman proposed a simple and intuitive thought experiment in favor of the existence of gravitational waves. This "sticky bead" argument presumably contributed to inspiring the pioneering experimental efforts by Joseph Weber. In fact, Feynman's qualitative argument was supported and extended by detailed calculations, several results of which were presented at Chapel Hill as well. While the original calculations are presumably lost, Feynman included a detailed description of an updated version of them in a letter he wrote to Viktor F. Weisskopf in early 1961.[9] These updated computations were also included in the famous graduate lectures on gravitation he delivered at Caltech in the academic year 1962-63.[7] They show that Feynman had addressed most of the contemporary theoretical problems of the subject, showing that gravitational waves carry energy, and that they can be detected by suitable instruments; moreover, he computed in detail the energy radiated by binary self-gravitating systems. Feynman's comments clearly show that he regarded his results as compelling (and probably somewhat straightforward as well, since he did not publish them) solutions to the above mentioned issues. Indeed, in his subsequent work on gravity, Feynman did not deal with gravitational waves any more, focusing instead on quantum gravity.

The paper is organized as follows. In Sect. 2 we briefly sketch the history of gravitational waves prior to Feynman's engagement with them, highlighting the theoretical problems which were the concern of scientists in the 1950s and 1960s. In Sect. 3 we briefly introduce the historical context in which the Chapel Hill conference took place and we summarize Feynman's contributions to it. In Sect. 4 we examine the letter to Weisskopf, and the parts of the Lectures on Gravitation which discuss gravitational waves. We close this section with a summary of Feynman's solutions to the theoretical issues in gravitational wave research. In Sect. 5 we give some comments on Feynman's work on gravitational waves, in particular in connection with his general views on gravity and on fundamental interactions in general.

[a] This was confirmed by Bryce S. DeWitt, who declared: "Even by 1955 Feynman claimed to have spent a great deal of effort on the problem of gravitation".[3]

In Sect. 6 we outline some contemporary and later developments, and in particular we describe the solutions to the theoretical issues that are currently accepted by the scientific community. Sect. 7 is devoted to conclusions.

2. Brief history of gravitational waves up to the 1950s

The main open problem concerning gravitational waves, when Feynman tackled them, was their very existence as physical entities.[b] In fact, general relativity enjoys general covariance, which means that coordinate systems have no intrinsic meaning. While very elegant and powerful, this symmetry also poses great difficulties, which have kept haunting general relativity practitioners since the earliest days of the theory. Namely, it is not easy to distinguish between real physical phenomena and mere artifacts due to a bad coordinate choice, hence invariant characterizations are needed. One of the earliest examples is the Schwarzschild singularity,[11] which occurs in the spherically symmetric solution found by Karl Schwarzschild. In fact, the metric describing this solution in spherical coordinates displays a singularity on a surface located at a given value of the radial coordinate. This singularity is now well-known to be apparent, and it is removed by choosing a different coordinate system,[12] but it took more than forty years to really understand what this meant. Two other, strictly linked examples, are given by the definition of energy in general relativity, and by gravitational waves themselves. When Albert Einstein first showed in 1916[13] that the gravitational field equations he had written down the year before[14] predict in the weak field limit the existence of wave-like excitations, and when in 1918[15] he corrected a major mistake in his 1916 paper, finding his celebrated quadrupole formula describing the leading-order energy emission through gravitational radiation, he chose a particular coordinate system, in which his equations looked formally analogous to the equations of electromagnetism. Einstein immediately recognized that some of the wave solutions he had found were spurious, and could be eliminated by a coordinate change (they were flat space in curved coordinates), while the remaining ones were not spurious, and carried energy according to his formula.

2.1. *The question of the existence of gravitational waves*

A weak point in Einstein's derivation was spotted and corrected by Sir Arthur S. Eddington,[16] namely, the fact that Einstein's choice of coordinates explicitly contained the speed of light, hence the propagation speed of gravitational waves may have been inadvertently put in by hand by the German physicist. Eddington improved and extended Einstein's work, giving a more rigorous proof of the fact that some of Einstein's solution were not coordinate artifacts, they carried energy and they propagated with the speed of light. Finally, Eddington rederived the

[b]For details on the history of gravitational waves, with a focus on the theoretical side, we refer to Ref. 10.

quadrupole formula, correcting a minor error by Einstein (an overall factor of 2), and applied it to the computation of energy radiated away by a rigid rotator. However, in complaining about the lack of an invariant way of distinguishing physical from spurious waves, Eddington referred to the latter in a very suggestive way, stating that, being coordinate artifacts, they propagate with the "speed of thought" (Ref. 17, p. 130). This generated a misunderstanding according to which Eddington attributed this characteristic to gravitational waves in general, thus questioning their very existence. Indeed, doubts concerning the existence of gravitational waves did not stop bothering the scientists working in general relativity for a long time. Another problem was posed by the fact that, unlike electromagnetism, gravitation is described by a highly nonlinear theory, while gravitational waves had been found only in the linearized approximation. The possibility thus existed that gravitational waves were in fact only artifacts of the linearized theory, meaning that there is no solution to the full gravitational field equations describing gravitational fields propagating as waves. This point of view was shared for some time by Einstein himself, after in 1937 he had tried with Nathan Rosen to find plane wave solutions to the full gravitational field equations.[18] Indeed, the two physicists found singularities in their solutions, and interpreted them as obstructions to the existence of propagating solutions to the equations.[c] After a well-known incident with a referee,[20] Einstein finally realized that the singularities he had found were coordinate artifacts, and that in fact he and Rosen had found an exact solution to his field equation, which enjoyed cylindrical symmetry. This was one of the first solutions to the full theory describing gravitational waves.[d] However, the question of the physical effects ascribable to these waves was still unclear, since it seemed that they did not carry energy, as still argued by Rosen himself in 1955 (Ref. 22, pp. 171-174), and anyway the Einstein-Rosen solution was non-physical, since its source was not localized. What was needed was an exact solution describing waves radiating from a localized center, which was still unavailable at the time. In any case, the fact that even Einstein himself had doubted that gravitational waves could exist certainly contributed to making them a neglected field of study for twenty more years.

A very important breakthrough occurred in 1956, when Felix A. E. Pirani managed to give an invariant characterization of gravitational radiation, in terms of spacetime curvature rather than energy,[23,24] giving in fact birth to the modern popular description of gravitational waves as propagating ripples of curvature. This work was performed in the context of Pirani's investigations of the physical meaning of the Riemann curvature tensor, based on the geodesic deviation equation[25] and on the classification of curvature tensors in terms of their principal null directions.[26] In particular, using the geodesic deviation equation, Pirani showed that the passage of a gravitational wave should modify the proper distance between test particles,

[c] Einstein mentioned this in a letter to Max Born (Ref. 19, letter 71).
[d] Actually, Einstein and Rosen had rediscovered a solution first found by Guido Beck in 1925.[21]

as an effect of the variation of the curvature. Thus, a measurable effect could be ascribed at least in principle to gravitational waves.

2.2. *The question of energy loss*

The issue of existence was not the only one which was at stake in gravitational wave physics in the 1950s. Even taking existence for granted, indeed, there was a problem concerning gravitational radiation by self-gravitating systems, such as binary stars. The first applications by Einstein and Eddington involved rigid bodies such as rotators, which can be considered to be kept together by the electromagnetic interaction, while a bound state kept together by gravity itself is beyond the reach of the linearized approximation, which was the only context in which gravitational energy radiation had been studied. In fact, many physicists even doubted that gravitational waves were radiated at all by such a system. And even if radiation did occur, it was unclear whether the Einstein quadrupole formula, which had been obtained in the linearized theory, correctly described the resulting energy loss. The issue had been addressed for the first time in 1941 by Lev D. Landau and Evgenij M. Lifshitz, in the first edition of their textbook,[27] where the binary system was treated by using the post-Newtonian approximation, and energy loss was computed by applying the quadrupole formula. However, there was no consensus about the correctness of their calculation, and the question was still open in the 1950s.

2.3. *Summary of the open problems*

From what we said above, it emerges that the situation concerning gravitational wave research was far from clear in the 1950s, with many basic theoretical problems and no hope of experimental guidance. We may summarize the main issues at stake as follows:

(1) The actual existence of gravitational waves as physical entities, their speed of propagation and their energy conveying;
(2) The existence of gravitational waves as solutions to the full nonlinear gravitational field equations;
(3) The radiation of gravitational waves by self-gravitating systems and the correctness of the quadrupole formula in describing the energy loss.

3. The Chapel Hill conference

As we saw, before the 1950s research on gravitational waves was carried out by only a handful of pioneers. This lack of interest was in fact not only the result of the doubts expressed by Einstein and also attributed to Eddington. The whole field of general relativity remained dormant for thirty years, from the mid-1920s to the mid-1950s, after an initial burst of activity. During this period, later baptized "low-watermark" phase,[28–30] general relativity was considered by most physicists to be

a rather esoteric and heavily mathematical subject, with tenuous relations with the physical world.

Around the mid-1950's, things began to change, and gravity slowly regained a prominent place in physics. Pivotal to this change of attitude, which was dubbed the "renaissance" of general relativity,[31–33] was the organization of a series of international conferences entirely devoted to the subject. The renaissance of general relativity was characterized by the fact that physicists began studying the theory in a less speculative fashion than before, by focusing on its physical implications, and by developing dedicated, i.e. intrinsically general relativistic methods. That was also a time where researchers from other fields, most notably particle and field theory, began to be interested on gravitation and to apply their methods to it. One of them was of course Feynman, who started working on gravity just in this period, and it was in one of these conferences, namely the one (organized by DeWitt and his wife Cécile DeWitt-Morette) at the University of North Carolina at Chapel Hill in January 1957,[4] that he first announced his results in the field, as we anticipated in the introduction. In his many contributions to the discussions at Chapel Hill, he clearly delineated his attitude towards gravity, and presented a host of results he had already obtained. Besides the arguments on favor of the existence of gravitational waves, which we discuss in the following subsections, Feynman sketched a proposal for a field-theoretical approach to classical gravity. His view, shared by other particle physicists, was indeed that gravity had to be regarded as a fundamental interaction like all the others, and hence it had to be described by a field theory, which would also encode quantum corrections to the classical theory. Indeed, within a few years, he managed to derive the field equations of general relativity (as summarized in Ref. 7), and he attacked the problem of quantum gravity, from this perspective.[6,8] Finally, the Chapel Hill conference is notably one of the few occasions where Feynman expressed his views about foundational quantum issues, which were inspired by the problem of the quantization of gravity.[4,6,8,34]

3.1. *The sticky bead argument*

Feynman presented his famous sticky bead argument in a session devoted to discussing the necessity of gravity quantization (in which he also proposed a thought experiment in order to argue in favor of that). In fact, Feynman had arrived a day later at the conference[e], skipping the session devoted to gravitational waves. However, further discussion of gravitational waves in sessions devoted to quantum gravity was not off-topic, since the existence of these waves is of course very important for the quantization of the theory. Thus, in the middle of a discussion about whether the gravitational field had to be quantized even in the absence of gravitational waves, Feynman proposed a simple physical argument in favor of their existence (Ref. 4, p. 260 and pp. 279-281). He argued that if gravitational waves

[e] An amusing and well-known recollection of his arrival in North Carolina can be found in Ref. 35.

exist, they must carry energy and this, together with the existence of these waves as solutions of the linearized theory, was enough for him to be confident in their existence. He expressed this intuitive feeling with the words: "My instincts are that if you can feel it, you can make it" (Ref. 4, p. 260). Feynman's reasoning was detailed in an expanded version of his remarks, included in the records of the conference[4]:

> I think it is easy to see that if gravitational waves can be created they can carry energy and do work. Suppose we have a transverse-transverse wave generated by impinging on two masses close together. Let one mass A carry a stick which runs past touching the other B. I think I can show that the second in accelerating up and down will rub the stick, and therefore by friction make heat. I use coordinates physically natural to A, that is so at A there is flat space and no field [...]. Then Pirani at an earlier section gave an equation for the motion of a nearby particle. (Ref. 4, p. 279).

The result by Pirani is of course that obtained in Refs. 23 and 24 (which indeed had been presented earlier at the conference, cf. Ref. 4, p. 141), stating that the displacement η of the mass B (measured from the origin A of the coordinate system) in the field of a gravitational wave satisfies the following differential equation:[f]

$$\ddot{\eta}^a + R^a_{0b0}\eta^b = 0, \qquad (a, b = 1, 2, 3) \tag{1}$$

R being the Riemann curvature tensor at the point A. Feynman continued:

> the curvature tensor [...] does not vanish for the transverse-transverse gravity wave but oscillates as the wave goes by. So, η on the RHS is sensibly constant, so the equation says the particle vibrates up and down a little (with amplitude proportional to how far it is from A on the average, and to the wave amplitude.) Hence it rubs the stick, and generates heat. (Ref. 4, p. 279)

The upshot is that the stick absorbs energy from the gravitational wave, which means that the latter carries energy and is able to do work.

3.2. *Feynman's theoretical detector*

In connection with the device he considered, Feynman went on considering a possible gravitational wave detector in which there are four, rather than two test masses, which oscillate as shown in Figure 1.

This thought device was used to compute how much energy gravitational waves would carry. The device was described by Feynman as follows:

> If I use 4 weights in a cross, the motions at a given phase are as in the figure (Fig. 1). Thus a quadrupole moment is generated by the wave. Now the

[f] This follows from the geodesic deviation equation (Ref. 4, p. 141; Refs. 23 and 24).

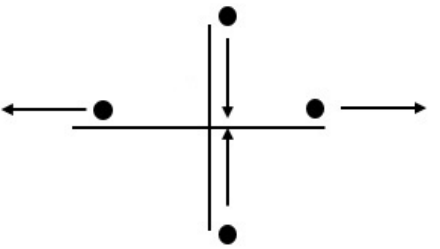

Fig. 1. Scheme of Feynman's gravitational wave detector.

> question is whether such a wave can be generated in the first place. First since it is a solution of the equations (approx.) it can probably be made. Second, when I tried to analyze from the field equations just what happens if we drive 4 masses in a quadrupole motion of masses like the figure above would do - even including the stress-energy tensor of the machinery which drives the weights, it was very hard to see how one could avoid having a quadrupole source and generate waves. Third my instinct is that a device which could draw energy out of a wave acting on it, must if driven in the corresponding motion be able to create waves of the same kind. [...] If a wave impinges on our "absorber" and generates energy - another "absorber" placed in the wave behind the first must absorb less because of the presence of the first, (otherwise by using enough absorbers we could draw unlimited energy from the waves). That is, if energy is absorbed the wave must get weaker. How is this accomplished? Ordinarily through interference. To absorb, the absorber parts must move, and *in moving generate a wave* which interferes with the original wave in the so-called forward scattering direction, thus reducing the intensity for a subsequent absorber. In view therefore of the detailed analysis showing that gravity waves can generate heat (and therefore carry energy proportional to R^2 with a coefficient which can be determined from the forward scattering argument). I conclude also that these waves can be generated and are in every respect real. (Ref. 4, p. 280, emphasis in the original)

In this quote, Feynman's point of view about the existence of gravitational waves is evident: since they exist as solutions of the field equations (albeit in the linearized approximation), they carry energy, and they can be generated (in fact, the detector generates secondary waves), then they must be a real phenomenon.

3.3. *Binary systems*

Within the discussion (Ref. 4, p. 260), Feynman also quoted a result concerning the calculation of the energy radiated by a self-gravitating two-body system in a circular orbit. This result shows that he had addressed also this issue, performing

detailed calculations. The quoted result is:

$$\frac{\text{Energy radiated in one revolution}}{\text{Kinetic energy content}} = \frac{16\pi}{15}\frac{\sqrt{mM}}{m+M}\left(\frac{u}{c}\right)^5, \tag{2}$$

where m and M are the masses of the two bodies, and u is their relative velocity. In the case of the Earth-Sun system, this formula describes as expected a tiny effect, leading to a huge order of magnitude (about 10^{26} years) for the lifetime of the motion of the Earth around the Sun. Despite the smallness of the effect, this is a definite prediction. Feynman stated to have performed a full analysis of this problem some time before (Ref. 4, p. 280), but he only quoted the result, without presenting his computations. Fortunately, Feynman reported a version of them four years later, in the letter written to Victor F. Weisskopf,[9] to which we now turn.

4. The letter to Weisskopf and the sixteenth lecture on gravitation

As anticipated, a complete and systematic description of Feynman's computations on gravitational waves can be found in a letter he wrote to Weisskopf in February 1961,[9] to answer a question that the Austrian physicist had asked him in the fall of 1960, concerning the reality of gravitational radiation. The letter was so detailed that it was subsequently included in the material distributed to the students attending the Caltech lectures in 1962-63. Indeed, the sixteenth lecture of that course (the last one in the published version[7]) dealt with gravitational waves, and reproduced part of the computations showed in the letter itself, with additional interesting comments.

The computations that Feynman reported in the letter and in the lectures were surely related to those he had performed before the Chapel Hill conference, but included several improvements that Feynman had conceived meanwhile. Indeed, at the end of the letter, he recalled the conference, claiming that

> It was this entire argument used in reverse that I made at a conference in North Carolina several years ago to convince people that gravity waves must carry energy. [...] Only as I was writing this letter to you did I find this simpler argument from the Lagrangian (Ref. 9, p. 14).

What Feynman meant by "argument used in reverse" and by "simpler argument from the Lagrangian" will be clear by the end of this section.

The most striking fact about the computations is that they are performed adopting a quantum point of view, treating general relativity as a quantum field theory, and then considering the classical limit:

> My view is quantum mechanical, but the classical limits are easily derived. (Ref. 9, p. 6)

Only later the same computation is repeated from the usual, classical point of view, in the framework of linearized gravity. As we saw, in fact, in that period Feynman

was struggling with the quantization of gravity, building on the field theoretical viewpoint that he had advocated at Chapel Hill. In the beginning of 1961, he had recognized that loop diagrams in the theory present major difficulties, but he was still far from a solution (later in the same year he would report on his progress at the La Jolla conference[36]). However, he could safely study classical gravity by applying his field theoretical methods to tree diagrams, which are the only ones relevant to the classical limit (while loop diagrams describe quantum corrections). This is what he did in the letter,[g] claiming that:

> I am studying the problem of quantization of Einstein's General Relativity. I am still working out the details of handling the divergent integrals which arise in problems in which some virtual momentum must be integrated over. But for cases of radiation, without the radiation corrections, there is no difficulty. (Ref. 9, p. 1)

The "radiation corrections" Feynman was referring to are of course what are usually called radiative corrections, i.e. higher order corrections to the processes, which include the troublesome loop diagrams. In fact, in the Lectures Feynman adopted this point of view in studying many other problems in classical gravity:

> All other problems in the theory of gravitation[h] we shall attack first by the quantum theory; in order to obtain the classical consequences on macroscopic objects we shall take the classical limits of our quantum answers. (Ref. 7, p. 163)

The field theoretical methods that Feynman used are intrinsically perturbative. Feynman explicitly discussed the validity of this approximation, and of the linearized approximation he used in the classical computation, stating that this is a natural and obvious choice in view of the extreme weakness of the gravitational interaction. He stated in fact that:

> I won't be concerned with fields of arbitrary strength [...]. I am surprised that I find people objecting to an expansion of this kind, because it would be hard to find a situation where numerically a perturbation series is more justified! (Ref. 9, p. 1)

which is confirmed in the Lectures:

> There needs to be no apology for the use of perturbations, since gravity is far weaker than other fields for which perturbation theory seems to make extremely accurate predictions. (Ref. 7, p. 207)

[g] A conceptually analogous calculation was performed in 1936 by Matvei Bronstein,[37] who derived the quadrupole formula with the correct factor of 2 by computing the emission coefficients of transverse gravitons.

[h] Here Feynman was referring to all problems, apart from that of a spherical mass distribution and cosmology.

From these quotations, it is evident that Feynman considered the contemporary debate around the existence of gravitational waves in the full nonlinear theory of general relativity, as opposed to the linearized theory, to be pointless, since the perturbative/linearized theory would furnish an excellent approximation in most cases of interest.[i]

4.1. *The quantum computation*

To perform his computation, Feynman started from linearized gravity, which from his point of view was the linear theory of a massless charged spin-2 quantum field coupled to matter. For simplicity, he considered scalar (spin-0) matter, and he computed the probabilities for single graviton emission in several processes involving matter particles, in the low energy limit. The result is that the probability of emission of a graviton with frequency ω in the solid angle $\mathrm{d}\Omega$ is (Ref. 9, p. 7; Ref. 7, p. 214):

$$P = a^2 \frac{\mathrm{d}\Omega}{4\pi} \frac{\mathrm{d}\omega}{\omega} \frac{\lambda^2}{4\pi^2}, \tag{3}$$

where a is a kinematical factor and λ is the gravitational coupling constant (which is proportional to the square root of Newton's constant G).

Feynman knew that the probabilities of radiation of massless quanta become universal in the low energy limit, i.e. the probability of emission of a soft quantum in an interaction is independent of the spin of the interacting quanta (hence the choice of scalar matter implies no loss of generality), and most importantly of the kind of interaction which is involved. This happens because the low-energy limit is equivalent to the long-wavelength limit, in which the physics is insensitive to short-distance details. In particular, soft graviton emission occurs, with the same probability, also when matter quanta interact gravitationally. Since classical radiation is related to soft quantum emission, the implication is that masses accelerating under the reciprocal gravitational interactions must emit gravitational radiation as any other accelerating mass:

> Although this was worked out for spin zero particles, the result, as $\omega \to 0$, is the same for all, spin 1/2, photons, etc. It is correct for collisions irrespective of the kind of force. For example, Schiff asked me if two masses under their mutual gravitation can radiate. The answer is certainly yes. (Ref. 9, p. 7)

According to Feynman, these results proved that self-gravitating system must radiate gravitational waves. This view was confirmed in the Lectures:

[i]He also acknowledged the fact that the problem was at the moment of purely academic interest, stating that "the most "practical" thing to do is to go to zero order and forget the whole problem altogether" (Ref. 9, p. 1).

> As far as the radiation is concerned, the exact nature of the over-all scattering process is not important. I emphasize the last point because there are always some theorists who go about mumbling some mystical reasons to claim that the radiation would not occur if the scattering is gravitational - there is no basis for these claims; as far as we are concerned, radiation of gravity waves is as real as can be; the sun-earth rotation must be a source of gravitational waves. (Ref. 7, p. 215).

Thus the issue of gravitational radiation by self-gravitating systems was considered solved by Feynman. We emphasize that his quantum point of view was pivotal to that conclusion, since his reasoning relied on a well-known result of quantum field theory, namely the universality of soft graviton emission. Once again, Feynman showed some annoyance towards the physicists who continued to have doubts, while the solution was so clear to him.

4.2. *The classical computation and the quadrupole formula*

In the second part of the letter, Feynman switched to a classical computation, which was considered to be more appropriate for macroscopic objects, such as celestial bodies:

> for the motion of big objects such as planets and stars it may be more consistent to work in the classical limit. (Ref. 7, p. 215)

The classical computation was developed in close analogy with electrodynamics, taking into account that in the case of gravitation the source is a tensor $S_{\mu\nu}$ rather than a vector J_μ. The differential equation which has to be solved to find classical gravitational waves is (in the notation of Ref. 7):

$$\Box^2 \overline{h}_{\mu\nu} = \lambda S_{\mu\nu}, \tag{4}$$

where $h_{\mu\nu}$ is the field describing deviations of the metric from the flat Minkowski metric and the bar operation is defined as:

$$\overline{h}_{\mu\nu} = \frac{1}{2}\left(h_{\mu\nu} + h_{\nu\mu}\right) - \frac{1}{2}\eta_{\mu\nu} h^{\sigma}{}_{\sigma}. \tag{5}$$

$\Box^2$ is the usual, flat-space, d'Alembertian operator. As well-known, the above equation corresponds to the linearized Einstein equations in the de Donder gauge $\partial^\mu \overline{h}_{\mu\nu} = 0$. When all quantities are periodic with a given frequency ω, the solution at a point 1 located at a distance from the source much greater than the linear dimensions of the source itself (which is the region where $S_{\mu\nu}$ is expected to be large):

$$\overline{h}_{\mu\nu}(\vec{r}_1) = -\frac{\lambda}{4\pi r_1} e^{i\omega r_1} \int d^3\vec{r}_2 S_{\mu\nu}(\vec{r}_2) e^{-i\vec{K}\cdot\vec{r}_2}, \tag{6}$$

with $|\vec{r}_1| \gg |\vec{r}_2|$ as stated. This approximation holds for nearly all cases of astronomical interests, where wavelengths are much longer than the system's dimensions,

such as for instance binary stars and the Earth-Sun system. Finally, Feynman assumed that the motions of matter in the source were slow, so that he could resort to the post-Newtonian approximation. This is where the computations in the last section of Lecture 16 of the Caltech Lectures (Ref. 7, pp. 218-220) stopped, while in the letter Feynman went on computing the power radiated by the above waves in the quadrupole approximation which, for a periodic motion of frequency ω, read (Ref. 9, p. 11):

$$\frac{\text{mean energy radiated}}{\text{sec.}} = \frac{1}{5} G\omega^6 \sum_{ij} \left| Q'_{ij} \right|^2 , \tag{7}$$

where $Q'_{ij} = Q_{ij} - \frac{1}{3}\delta_{ij} Q_{kk}$, $Q_{ij} = \sum_a m_a R^a_i R^a_j$ is the quadrupole mass moment, and the root mean square average is taken. The result (7) was then shown to agree with the quantum mechanical probability (3) computed in the first part of the letter (after suitable averaging). To strengthen this result, Feynman had considered earlier (Ref. 9, p. 10) an analogous comparison for the case of electromagnetism, finding again perfect correspondence.

Feynman then applied his formulas to the case of a circularly rotating double star (Ref. 9, p. 12), promptly recovering the result (2). In sum, Feynman's classical computation was analogous to that performed earlier by Landau and Lifshitz. However, his treatment was simpler, since he managed by using a very ingenious method for computing the energy density, which essentially exploits the fact that for classical transverse plane waves the linearized gravity Lagrangian reduces to that of the harmonic oscillator. This spared him formal complications such as the cumbersome energy-momentum pseudo-tensor, which was used by Landau and Lifschitz. This is in fact the "simpler argument from the Lagrangian" which he referred to in the end of the letter.

The above treatment was then supplemented with a thorough analysis of the effects of a gravitational wave impinging on a device made of two test particles placed on a rod with friction, in this way providing a more complete description of the working principle of the gravitational wave detector previously introduced at Chapel Hill. A second absorber, made of four moving particles in a quadrupole configuration, as in Figure 1, was also considered, and shown to be able to absorb energy from a gravitational wave acting on it. The oscillating device was shown to re-radiate waves with the same energy content. Apparently, at Chapel Hill, Feynman had derived the expression for the radiated energy (which was then applied to the binary system case) from the detailed study of the quadrupolar detector, either because at that time he did not know how to extract the definition of energy from the gravitational Lagrangian, or because the existing methods were considered to be too cumbersome by him. In the letter, instead, Feynman found a simple way of taking the opposite route (from this we can understand why Feynman claimed that the argument at Chapel Hill had been "used in reverse"), since the quadrupole formula was derived in general from the linearized Einstein equations and then applied to the detector case.

Thus, Feynman had shown that gravitational waves carry energy, and he had computed how much, also in the case of a binary star, satisfactorily addressing both the first and the third of the above issues. At the end of Lecture 16 of Ref. 7, Feynman commented again on the energy content of gravitational waves:

> What is the power radiated by such a wave? There are a great many people who worry needlessly at this question, because of a perennial prejudice that gravitation is somehow mysterious and different - they feel that it might be that gravity waves carry no energy at all. We can definitely show that they can indeed heat up a wall, so there is no question as to their energy content. The situation is exactly analogous to electrodynamics (Ref. 7, p. 219).

and in the letter, while recalling the Chapel Hill conference he commented:

> I was surprised to find a whole day at the conference devoted to this question, and that "experts" were confused. That is what comes from looking for conserved energy tensors, etc. instead of asking "can the waves do work?" (Ref. 9, p. 14).

These two quotes again display Feynman's annoyance towards the relativity community. The fact that relativists kept arguing about these problems without reaching an agreement, and that they privileged sophisticated formal tools to plain physical thinking, definitely disturbed Feynman, who repeatedly expressed his annoyance, and may have contributed to his loss of interest in the subject.

4.3. *Feynman's answer to the three issues*

The detailed study of Feynman's work on gravitational waves reveals what he thought the solutions to the issues listed in Sect. 2 should be, at least from a theoretical point of view, pending the ultimate experimental verification. In summary, these were:

(1) Feynman's thought experiments and calculations clearly show that gravitational waves exist and that they carry energy, while the fact that they propagate with the speed of light is a consequence of the fact that they emerged from massless quanta, i.e. the gravitons;
(2) Since gravity is so weak, it makes perfect sense to study gravitational waves using the linearized approximation;
(3) Gravitationally-bound system emit gravitational radiation as any other bound system, and the energy loss is described by the quadrupole formula in the approximations valid in most situations of interest.

5. Comments on Feynman's attitude towards gravity and gravitational waves

As emphasized, Feynman's approach to gravitational waves, and to gravitation in general, was much closer in spirit to particle physics than to general relativity. In fact, Feynman preferred a field theoretical approach over the geometrical one which had become the standard one among relativists. In his opinion, indeed, the latter approach divided gravity from other fundamental interactions, preventing the investigation of the relation of gravitation with the rest of physics, and also posing great obstacles towards its quantization.

A second motivation which underlies Feynman's choice of using quantum field theoretical methods for investigating classical gravitational radiation and other problems in classical gravity, was his belief that quantum mechanics underlies Nature at the most fundamental level, with the forces we observe at the macroscopic level emerging from quantum interactions in the classical limit. This is most clearly expressed by him in some unpublished lectures:

> I shall call conservative forces, those forces which can be deduced from quantum mechanics in the classical limit. As you know, Q.M. is the underpinning of Nature... (Ref. 38, p. 35)

Feynman recognized that the main problem with gravity was the fact that general relativity had received only a handful of experimental confirmations, while the subjects of gravitational waves and quantum gravity were confined to pure theory. These subjects were being investigated by the relativity community by resorting to sophisticated mathematics, in the hope that rigor could be a substitute for empirical evidence. Feynman had a different point of view. To him, the best way to proceed was to try to extract physical predictions from the theory *as if* these were easily accessible experimentally. This viewpoint was strongly advocated by him at Chapel Hill in some critical comments:

> There exists, however, one serious difficulty, and that is the lack of experiments. [...] so we have to take a viewpoint of how to deal with problems where no experiments are available. There are two choices. The first choice is that of mathematical rigor. [...] The attempt at mathematical rigorous solutions without guiding experiments is exactly the reason the subject is difficult, not the equations. The second choice of action is to "play games" by intuition and drive on. Take the case of gravitational radiation. [...] I think the best viewpoint is to pretend that there are experiments and calculate. In this field since we are not pushed by experiments we must be pulled by imagination. (Ref. 4, pp. 271-2)

and shortly after

> The real challenge is not to find an elegant formalism, but to solve a series of problems whose results could be checked. This is a different point of view. Don't be so rigorous or you will not succeed. (Ref. 4, p. 272)

This is in fact the viewpoint that Feynman adopted in his investigations of gravitational waves, but also in his work on quantum gravity.[8]

6. Contemporary and subsequent developments

When the Chapel Hill conference took place, the time was ripe for the existence of gravitational waves to be accepted by most physicists. Thus, the work of Pirani, and Feynman's sticky bead argument, managed to convince people that gravitational waves belong to the realm of physical phenomena, and suggested ways to investigate their physical effects. In fact, an argument similar to Feynman's was conceived independently by a leading relativist, Hermann Bondi, who was also present at Chapel Hill. This is referred to by several of Bondi's remarks at the conference, such as the following one, made after Pirani's talk (Ref. 4, p. 142): "Can one construct in this way an absorber for gravitational energy by inserting a $d\eta/d\tau$ term, to learn what part of the Riemann tensor would be the energy producing one, because it is that part that we want to isolate to study gravitational waves?". The absorber of gravitational energy is just a more formal description of the "stickiness" of Feynman's sticky-bead. Shortly after the conference, Bondi published his variant of the sticky-bead device,[39] although unlike Feynman he did not succeed in relating the intensity of the gravitational wave to the amount of energy carried by it. Inspired by these discussions, another participant to the conference, Joseph Weber, soon undertook his lifetime effort to experimentally detect gravitational waves[40]; Weber built his famous resonant bar detector in 1966[41] and even announced the first experimental detection of gravitational waves coming from the center of the Milky Way in 1969.[42] While this finding was later disproved, Weber's works triggered all the subsequent research on the detection of gravitational waves, which culminated in the monumental detections by the LIGO-Virgo collaboration in 2016.[43] Among all the physical results that this brought about, the confirmation came that gravitational waves move with the speed of light.[44]

Thus, it may be said that the first issue, that of the existence and physical effects of gravitational waves, was solved after Chapel Hill, with agreement among the scientific community. The same cannot be said of the other two issues. The relativity community reached an agreement on the status of gravitational waves in the full nonlinear theory only some years later, thanks to the rigorous work performed in that framework by Bondi, Pirani, Ivor Robinson and Andrzej Trautman, among others. In particular, Robinson and Trautman found exact solutions to the equations of

general relativity describing waves radiated from bounded sources.[45] Furthermore, in the sixties, Bondi, Rainer W. Sachs, Ezra T. Newman and Roger Penrose,[46–50] gave a satisfactory definition of the energy radiated at infinity as gravitational radiation by an isolated gravitating system in an asymptotically flat spacetime. Thus, the modern theoretical characterization of gravitational waves had emerged by the late 1960s.

The last issue took still longer to be settled, since it crucially involved the problem of motion in general relativity and the issue of radiation reaction, whose foundations were still quite shaky.[51] The doubts concerning whether binary systems radiated gravitational energy were fought by crucial empirical input, which came in the mid-1970s with the discovery of the first binary neutron star.[52,53j] This did not immediately settle the quadrupole formula controversy yet,[54] but it prompted many efforts towards its resolution. The confirmation of came when Thibault Damour[55] showed that there was quantitative agreement between the emission rate computed from the quadrupole formula and observations. In fact, it is only in the final stages of the merging of compact objects that higher (mass and current) momenta need to be included (see e.g. Ref. 56 and references therein).

7. Conclusions

In the above pages, we have described the work performed by Richard Feynman in the physics of gravitational waves. We have seen how his attitude towards physics, and towards fundamental interactions, shaped this work, and how he managed to give sound and substantially correct answers to the main theoretical problems of the time. Feynman's physical intuition and sound calculations convinced him early on of the existence of gravitational waves and gravitational radiation. His work contributed to the settlement of the issue, and played a role in triggering the first experimental efforts towards their detection. Feynman did not share the theoretical concerns of most relativists, who continued to argue about other issues, until rigorous solutions and/or experimental input were available, and considered those arguments pointless, harshly criticizing them. This may have been contributed to his loss of interest in the subject, starting from the late 1960s, when he began to be involved to the only fundamental interaction to whose understanding he had not contributed yet, that is, the strong interaction.[5] But that is another story.

Acknowledgments

The authors would like to thank the staff of the Caltech archives for providing them a copy of Feynman's letter to Weisskopf.[9]

[j]In fact, so far, all direct and indirect evidence for gravitational waves has come from binary systems, which hence are the only confirmed sources.

We review three definitions (missing point(s) unsteadiness, infinite quadratic curvature invariant, and geodesic incompleteness) of what a gravitational singularity is, and argue that prediction of a gravitational singularity is problematic for General Relativity (GR), indicating breakdown of Lorentzian geometry, only insofar as it concerns the infinite curvature singularity characterization. In contrast, the geodesic incompleteness characterization is GR's innovating hallmark, which is not meaningfully available in Newtonian gravity formulations (locally infinite density field, and locally infinite gravitational force) of what a gravitational singularity is. It is the continuous, non-quantized, nature of Lorentzian geometry which admits gravitational contraction be continued indefinitely. The Oppenheimer-Snyder 1939 analytical solution derives formation of a locally infinite curvature singularity *and* of incomplete geodesics, while Penrose's 1965 theorem concerns formation of incomplete (null) geodesics only. We critically examine the main physical arguments against gravitational singularity formation in stellar collapse, with scope restriction to decades spanning in between Schwarzschild's 1916 solution and Penrose's 1965 singularity theorem. As the most robust curvature singularity formation counter-argument, we assess Markov's derivation of an upper bound on the quadratic curvature invariant $R_{\mu\nu\lambda\delta}R^{\mu\nu\lambda\delta} \leq \frac{1}{\ell_P^4}$ from a ratio of natural constants $\hbar$, c and G, in connection with Wheeler's grounding of the premise that the Planck scale ℓ_P is ultimate.

Keywords: Geodesic incompleteness; Infinite curvature; Schwarzschild incompressible fluid; Einstein-Rosen bridge; ISCO; Chandrasekhar mass; TOV mass; Core collapse; Compact stars; Oppenheimer-Snyder collapse; Singularity theorems; Curvature bound; Theory breakdown.

1. Characterization of a gravitational singularity

Over the period of over hundred years, the idea that gravitational singularity formation, predicted by General Relativity, is physical - representing a genuine feature of reality - was iteratively regarded with skepticism. The scientific community's doubts at times were based on mere conceptual reservation and reluctance to accept a novel paradigm, while at other times had justification by strong physical argument. In Sec. (1), we will outline how (not) to conceive what a gravitational singularity in General Relativity is, and compare two contrasting interpretational

views: realism and anti-realism about singularity formation. We will provide a simple field-theoretical argument in favour of the interpretation of the prediction of curvature divergence as an indication of theory breakdown in Sec. (1.3). The goal of the subsequent Sections (2) and (3) is to explore some of the main arguments that have historically (with a scope restriction to 1916-1965) been advocated as preclusions to gravitational singularity formation in stellar collapse, and to assess their relevance for the present.

1.1. *Coordinate vs. geometric singularity*

A first important propaedeutic worth a recall is the demarcation between a coordinate singularity and a geometric singularity. Let $(\mathcal{M}, g_{\mu\nu})$ be an ordered pair, with $\mathcal{M}$ a manifold, associated with a spacetime, and $g_{\mu\nu}$ a Lorentzian metric with signature $(-,+,+,+)$, defined on the manifold $\mathcal{M}$ and associated with geometric properties of the spacetime. A coordinate singularity indicates the limit of applicability of a coordinate chart to represent a metric tensor $g_{\mu\nu}$. The line element ($ds^2 = g_{\mu\nu}\, dx^\mu\, dx^\nu$) of the single-parameter (M, associated with mass) Schwarzschild metric in the Schwarzschild spherical coordinate chart $(x^0, x^1, x^2, x^3) = (ct, r, \theta, \phi)$ reads

$$ds^2 = -\left(1 - \frac{2GM}{r}\right) dt^2 + \left(1 - \frac{2GM}{r}\right)^{-1} dr^2 + r^2 g_\Omega. \tag{1}$$

As $r \to 2GM$, the radial component $g_{rr} \to \infty$ while the temporal component $g_{tt} \to 0$. Yet, the Gullstrand-Painlevé, the Kruskal-Szekeres and the Eddington-Finkelstein coordinates are examples of coordinate systems for which the Schwarzschild metric, when transformed onto another coordinate chart ($ds'^2 = g'_{\mu\nu}\, dx'^\mu\, dx'^\nu$), is regular at the Schwarzschild boundary (which, in Schwarzschild coordinates, locates at the $r = 2GM$ two-sphere) of the set of nested round spheres. To illustrate, the line element in Eddington-Finkelstein coordinates (v, r, θ, ϕ) reads

$$ds^2 = -\left(1 - \frac{2GM}{r}\right) dv^2 \pm 2\, dv\, dr + r^2 g_\Omega \tag{2}$$

where a tortoise coordinate $r^* = r + 2GM\, ln|\frac{r}{2GM} - 1|$ is introduced, satisfying $\frac{dr^*}{dr} = \left(1 - \frac{2GM}{r}\right)^{-1}$, to define the time-advanced ingoing (for $v = t + r^*$) and time-retarded outgoing (for $v = t - r^*$) coordinates, respectively. Representation of the Schwarzschild metric in Eddington-Finkelstein coordinates shows curves to be extendible beyond the Schwarzschild boundary. According to the Principle of General Covariance, coordinate systems play no role in the formulation of fundamental laws of physics; they only have a descriptive-representational role. No observer, and therefore no coordinate system is privileged over another, yet the capability of physical representation by one coordinate chart may break down while others do not: an illucidating GR-independent example is the failure of representation of the North (at $\theta = 0$) and of the South Pole (at $\theta = \pi$) by spherical coordinates, while their representation is regular in cartesian coordinates. In GR, changing a

coordinate chart implies a re-definition of the coordinate axes relative to a proper inertial frame. While the introduction of a new coordinate chart allows to transform away the apparent singularity at the Schwarzschild boundary $r = 2GM$, the central metric field irregularity at $r = 0$ persists in the maximally extended Schwarzschild spacetime. The Kretschmann scalar curvature invariant is a coordinate-independent measure that allows to identify a curvature singularity in the geometry of the metric field. It is defined as full contraction of the Riemann tensor with itself, summing over all of its components:

$$K = R_{\mu\nu\lambda\rho}R^{\mu\nu\lambda\rho}. \tag{3}$$

Its evaluation on the Schwarzschild metric yields $K = \frac{48G^2M^2}{r^6}$, which is finite at the Schwarzschild boundary $r = 2GM$, but divergent at $r = 0$.

1.2. *Missing point(s) unsteadiness, infinite quadratic curvature invariant, or geodesic incompleteness?*

Calculation of the Kretschmann scalar is one method to tell apart a genuine singularity in the geometry of the metric field from a mere coordinate singularity pertinent to a coordinate representation of the metric. There has, however, been debate over what the appropriate definition of a gravitational singularity is, which appropriately characterizes it physically. In particular, as summarized and cross-examined in Ref. 1, three different main conceptions (all of which have sub-classes) have been proposed:

(1) missing point(s) unsteadiness,
(2) infinite curvature, and
(3) path inextendibility.

Missing point(s) unsteadiness. The conception that a gravitational singularity is a missing point, or a set of missing points, on the spacetime manifold, suggests that a spacetime is singular if it contains a 'hole'.[2] Then, the metric field $g_{\mu\nu}$ is discontinuous at a point $p \notin \mathcal{M}$ or a set of points $\{p_i\} \notin \mathcal{M}$, which have been removed from the $\mathcal{M}$ spacetime manifold, akin to a tear in a piece of cloth. Conceptually, a missing point on the spacetime manifold suggests the absence of spacetime itself at that point. The motivation for this singularity characterization stems from the fact that derivative operators, such as the Riemann tensor, are locally ill-defined at points at which the metric field $g_{\mu\nu}$ is discontinuous - at points that lie outside of its domain. The demand that the metric is continuous and differentiable everywhere formalizes into the requirement of non-degeneracy: $det(g_{\mu\nu}) \neq 0$. The condition is fulfilled if all the components of both the covariant ($g_{\mu\nu}$) and the contravariant ($g^{\mu\nu}$) metric tensor are regular. Then, a (removable) gravitational singularity violates the steadiness condition for any choice of coordinate chart: the missing point, or points, on the spacetime manifold give rise to the impossibility of its smooth

local extension, and thereby to unsteadiness in the gravitational field. This historically original notion of a gravitational singularity has been deployed in the works of Schwarzschild, Einstein, Hilbert, and contemporaries.

The missing point(s) singularity definition suggests that the singular spacetime manifold could be 'patched' by the appendage of the boundary that embeds the singularity. The main burden to accepting this notion of singularity is that the boundary construction in the neighbourhood of the singularity turns into the location problem[1]: there is no Lorentz-covariant location of the missing point(s) on the spacetime manifold, which would be coordinate- and therefore observer-independent. Assuming that there are no more additional dimensions to the spacetime, there is no way of imagining it being embedded in a larger topological space, with respect to which one could identify the locations of the subspace point(s) to be missing out.

Infinite quadratic curvature invariant. There are many sub-classes to definitions of a gravitational singularity in terms of an infinite curvature pathology. They differ in choice of the curvature tensor and of the divergence criterion. One of the curvature singularity classes is identified by the Kretschmann scalar, a quadratic curvature invariant defined with the Riemann tensor. It is used as an indicator of the presence of a local curvature singularity, when $K \to \infty$. A local observer is then subject to tidal forces that arise from the differences in "strength" of the gravitational field between two neighbouring points in space-time, and the curvature singularity manifests in its growth without bound. However, a well-behaved quadratic curvature invariant does not imply that all other local curvature measures are regular: there are examples of space-times where the quadratic Riemann curvature invariants are vanishing but the Ricci curvature tensor $R_{\mu\nu}$ diverges.[3] Again others, such as the conformal Misner singularities, where curvature scalars are well-behaved but the Riemann tensor evaluated with some local tetrad is divergent. Yet the advantage of curvature tensor *products* over curvature tensors is the former's coordinate-independence.

A problem with a local curvature singularity characterization, even if defined by virtue of curvature tensor products, is that it is incomplete: there are examples of well-defined space-times in which the state of motion of the observer is decisive in determining the physical response, as the putative singularity is traversed: whether or not an object is rotating about its axis, or subject to proper acceleration in the direction of motion, determines whether the object gets torn into pieces by infinite tidal forces, or whether it survives the cross-over.[4] In the latter example, the curvature pathology arises for a non-rotating observer resting on a geodesic, and an improved local gravitational singularity definition needs be reformulated accordingly. However, even this extension of the singularity definition is insufficiently precise, given a number of counter-examples: a point in spacetime may be well-defined for an observer travelling on a complete geodesic and experiencing well-behaved tidal forces all the way along, while this same point exhibits a curvature

pathology for an observer travelling on an incomplete geodesic.[3] Finally, therefore, the most general gravitational singularity definition that aims to invoke a locally infinite curvature invariant needs to confess that the curvature pathology arises locally along a curve that is incomplete. This raises the question whether infinite curvature is even a necessary feature of a gravitational singularity, rather than an inessential singularity property, since the formation of an incomplete path may entail but does not require a curvature pathology. The relation between curvature divergence and geodesic incompleteness remains a delicate problem that still seeks its resolution in Lorentzian differential geometry, but for which there seem to be two options:

(1) a gravitational singularity is defined by geodesic incompleness (or, more generally, path inextendibility) alone. It does not imply divergence of any local curvature measure, which is an additional feature, realized in some singular spacetimes but not in others.
(2) a gravitational singularity is defined by geodesic incompleteness concurring with a locally divergent quadratic curvature invariant; curvature divergence endows geodesic incompleteness with a physical (and local) characterization.

Important conclusions can be drawn from comparison of the curvature singularity characterization in Einstein's gravity theory to the Newtonian gravity theory counterpart. The formulation of the Raychaudhuri-Komar singularity theorem[a] in the framework of Newton-Cartan gravity,[8] a geometrized tensor reformulation of Newtonian gravity theory suggests that

- in Newtonian gravity[b], curvature divergence (as measured by the geometrized Poisson equation $R_{\mu\nu}\xi^\mu\xi^\nu = 4\pi\rho$ where ξ^μ is an arbitrary time-like vector) arises as consequence of a locally (infinite density) pathology in the stress-energy field, which is source of the gravitational field, while

[a]The Raychaudhuri-Komar singularity theorem[5,6] predicts formation of an infinite matter density singularity from generic conditions. It applies to a perfect fluid (described by the stress-energy tensor in the form of eq. (11)), whose timelike ($u^\mu u_\mu = -1$) velocity field u^μ is geodesic and non-rotational. If the derivative of the divergence $\theta \equiv \nabla_\mu u^\mu$ along the geodesic congruence is positive (negative) at an instant of time and the convergence condition $R_{\rho\nu}u^\rho u^\nu \geq 0$ holds, then the energy density ρ of the fluid diverges in the infinite past (future) along every integral curve of u^μ. The above mentioned modern formulation of the theorem is taken from Ref. 7.

[b]The key difference is the following: while in Newtonian gravity a gravitational force field singularity may arise only as consequence of a pathological infinite energy density matter state, Einstein's gravity theory allows for formation of gravitational singularities in a vacuum ($T_{\mu\nu} = 0$), analytically as solutions to the vacuum Einstein Field Equations. A generic example is the collision of two plane gravitational waves ($R_{\mu\nu} = 0$) in an otherwise flat background. Tipler's general plane-wave singularity theorem[9] proves the collision spacetime be future null geodesically incomplete. In addition, in the collision region of the 'sandwiched' GWs, under certain conditions (which depend on polarization of the colliding GWs) a curvature singularity may form at the focused point, or a coordinate singularity instead, along with a Killing-Cauchy horizon.[10–12]

- geodesic incompleteness is a pathology in the gravitational field itself, independent of pathology or non-pathology of a matter state. This singularity characterization is not meaningfully available in Newtonian gravity theory.[c]

This distinction reminds of the interest to enquire not only about how a singularity is defined, but also how it is generically formed under physical conditions.

Geodesic incompleteness. The definition of a gravitational singularity in terms of geodesic incompleteness is the least problematic and most widely accepted singularity characterization. In contrast to a complete geodesic that is continued indefinitely, an incomplete path has a finite affine length parameter (which is proper time τ, for a time-like vector field). One of the ways to formalize geodesic completeness reads as follows:

> *A spacetime is singular if it contains an incomplete causal geodesic* $\gamma : [0, a) \to \mathcal{M}$ *such that there is no extension* $\gamma' : \mathcal{M} \to \mathcal{M}'$ *for which* $\gamma' \circ \gamma$ *is extendible.*[13]

The demand for unique geodesics that do not cross implies that the causal geodesic is not well-defined beyond the affine length a, at which the affine parameter converges. A relativistic spacetime $(\mathcal{M}, g_{\mu\nu})$ is timelike ($\gamma^\mu\gamma_\mu = -1$), null ($\gamma^\mu\gamma_\mu = 0$), or spacelike ($\gamma^\mu\gamma_\mu = +1$) geodesically incomplete if it entails an incomplete timelike, null, or spacelike geodesic, respectively. The example of the Taub-NUT space-time shows that a space-time can be time-like complete but null-incomplete, and vice versa.[14] Geodesic incompleteness implies that the worldline of a freely falling observer terminates, with no possibility of further extension.[d] A background presupposition of path inextendibility is that the spacetime in the theory is *maximally extended* and that it does not form a subset of a larger dimensional, more extensive geometry into which the manifold (e.g., a four-dimensional spacetime) is embedded.

1.3. *Theory breakdown?*

Singularity realism vs. anti-realism. The above mentioned three gravitational singularity definitions in General Relativity are conceptually quite distinct pathologies in the geometry of the gravitational field, and do not imply one another: missing point(s) unsteadiness singularity suggests the (local) absence of spacetime itself,

[c] See Ref. 8 for an opposing view. According to our assessment, the author confounds the geodesic incompleteness characterization of a gravitational singularity in Newton-Cartan gravity with that of the missing point(s) unsteadiness.

[d] In Refs. 1, 15, 16 a more inclusive *b-incompleteness* criterion is advocated as gravitational singularity definition. According to b-incompleteness, the inextendible path can but does not need be a geodesic: A maximal spacetime is singular if and only if it contains an inextendible path of a generalized affine length. Since every incomplete geodesic is b-incomplete, the geodesic incompleteness characterization is sufficient for the argument of this paper.

while an infinite quadratic curvature invariant suggests that tidal forces become infinite at a point in space-time, which itself may be well-defined on the manifold. Geodesic incompleteness suggests the finitude of worldlines in a spacetime, which nevertheless may be well-defined and endowed with well-behaved finite quadratic curvature invariants at any point on the manifold.

The predictions of gravitational singularities by General Relativity can, for each of the singularity classes separately, be physically interpreted in one of the two ways: either as

(1) a theory deficiency, or as
(2) opening up a profoundly novel viewpoint of properties of space-time geometry.

The stance of singularity realism is supported by arguments such as the empirical success of General Relativity as the predictive theory, and the reasoning that the prediction of -say- geodesic incompleteness does not prima facie logically imply any contradiction or internal inconsistency within the gravitation theory. The realist stance is also inclined to accept a gravitational collapse singularity as part of the definition of a Black Hole.

In contrast, the stance of singularity anti-realism is supported by lessons learnt from the pre-history of radical theory changes in physics, which teach us to only partially confess to the belief in some statements made by the current best physical theory, but not in others. Of particular concern are the prior experiences with singularities, in ray optics, in phase transition hydrodynamics, in Newtonian N-body gravitational dynamics, in Maxwellian electromagnetism and in other subfields of physics[e], all of which nail down the appearance of a *divergent quantity* as an artifact of the mathematical model that is deployed. Anti-realism about gravitational singularities in GR is supported by the mathematical ill-definition and non-differentiability of geometrical quantities, as far as the infinite curvature characterization is concerned. The relevance of the argument is demonstrated below upon the example of the electromagnetic interaction potential between two fermionic charges.

Theory change: The case of Electromagnetism. In classical electromagnetism, the Coulomb potential between two point masses carrying electromagnetic charges q_1 and q_2 reads

$$V(r) = -\frac{1}{4\pi\epsilon}\frac{q_1 q_2}{r}, \tag{4}$$

where r is the relative distance between the point masses. For vanishing distance $r \to 0$, the interaction potential $V(r)$ diverges. The physics of the electromagnetic interaction is, however, inappropriately described by the classical Maxwellian field theory at small relative distances at scale of order of magnitude of the de Broglie wavelengths of the charged particles. Here, effects of their quantum nature become non-negligible, and Quantum Electrodynamics takes over as descriptive theory

[e]See Ref. 19 for a brief discussion of some of the above mentioned examples.

instead: the basic interaction potential between two fermion charges Q_1 and Q_2 in Minkowski space-time $\eta_{\mu\nu}$ and the relative wave-vector $\mathbf{k}$ turns into the integral

$$V(r) = -\frac{-g^2\hbar c Q_1 Q_2}{4\pi}\frac{1}{(2\pi)^3}\int d^3k\; e^{\frac{i\mathbf{k}\cdot\mathbf{r}}{\hbar}}\frac{4\pi\eta_{\mu\nu}}{k^2}. \tag{5}$$

The upshot from this comparison is that the prediction of a singularity qua divergency in the interaction potential marks the limits of an empirically adequate applicability of a theory: it arises as an artifact of the theory description at coarse-grained scale. Similarly, General Relativity is a classical field theory that describes the phenomenology of gravitation at a macroscopic scale at which principles of classical physics apply. However, gravitational collapse - which is central subject of this work- involves processes in the strong gravity regime at microscopic scales $\delta r \to 0$, at which GR is not tested as gravitation theory, and hence lacks the basis for trust in its predictions.

2. Singularities in the interior Schwarzschild metric (1916–1939)

2.1. *Schwarzschild's incompressible fluid model, and Einstein's singularity resolution attempts*

Infinite pressure requirement. In his first 1916 paper,[20] Schwarzschild derives an analytical solution to the gravitational field *exterior* to a gravitating point mass, completing earlier work of approximated solutions found by Einstein. Eq. (1) is a simplified writing of the metric due to Droste[21] who found the same solution independently, that renounces from redundant variable transformations, and where the radial coordinate r is defined as a radial measure away[f] from the point mass M. In contrast, in his second 1916 publication[22] he calculates[g] the gravitational field *inside and outside* of, not a point mass, but of a static non-rotating spherically symmetric incompressible fluid. The externally measured radius of the fluid sphere is given by $P_a = \sqrt{\frac{3}{\varkappa\rho_0}}\sin\chi_a$, and internal properties of the fluid are supposed to give rise to an inner pressure source $P(r)$. In order to calculate the pressure distribution, Schwarzschild proceeds by imposing a Hydrostatic Equilibrium (HE) condition and the vanishing pressure boundary condition $P(P_a) = 0$ onto the fluid. From there, he finds an analytic expression to the pressure gradient $P(\chi) = \rho_0\left(\frac{2\cos\chi_a}{3\cos\chi_a - \cos\chi} - 1\right)$ be proportional to the density and to $v = \frac{2}{3\cos\chi_a - \cos\chi}$ which Schwarzschild refers

[f] Note that a covariant measure of spatial distance between two nested spheres at r_1 and r_2 is obtained from the proper distance $\varrho = \int_{r_1}^{r_2} dr\,\sqrt{g_{rr}}$.

[g] The line element of the interior Schwarzschild solution in the original coordinates used by Schwarzschild takes the non-trivial form:

$$ds^2 = \left(\frac{3cos\chi_a - cos\chi}{2}\right)^2 dt^2 - \frac{3}{\varkappa\rho_0}(\chi^2 + sin^2 d\theta^2 + sin^2\chi\, sin^2\theta\, d\phi^2). \tag{6}$$

Schwarzschild derives a metric with two independent parameters (χ_a and ρ_0) associated with internally measured radius and density of the incompressible fluid, respectively. Here, $\varkappa = 8\pi k^2$ where k is the Gaussian gravitation constant.

to as the "*naturally measured light velocity*".[22] After a critical matter concentration threshold[h] is surpassed, v, and thereby also the pressure, diverge at the center ($\chi = 0$). There, the gravitational field becomes infinite, and introduces a discontinuity into metric $g_{\mu\nu}$. From his calculation follows the requirement of an infinite pressure at the center of the sphere in order to maintain its HE, which he evaluates as physically unacceptable, and as a breakdown of the incompressible constant density fluid model. He summarizes his finding as follows:[i]

> "*In the center of the sphere ($\chi = 0$) the speed of light and pressure become infinite, as soon as* $\cos\chi_a = 1/3$*, and as the fall velocity has become equal to* $\sqrt{8/9}$ *of the (naturally measured) speed of light. Therewith a limit of concentration is given, beyond which the sphere of incompressible fluid may not exist. Applying our equations to* $\cos\chi_a < 1/3$*, one would obtain unsteadiness already above the center of the sphere [...]. Over these solutions, which indeed are physically meaningless, since they result in infinite pressure in the center, one can pass over to the limiting case of a mass concentrated at a point [...]. For an externally measuring observer follows (...) that the sphere of given gravitational mass* $\alpha/2k^2$ *may have no smaller externally measured radius than* $P_a = \alpha$*.*"[22]

The Newtonian central singularity counterpart, and pragmatism on the "impassible barrier". In Droste's coordinates, Schwarzschild's analytical 1916 solution entailed the prediction of two irregularities: the central singularity at the center of the incompressible fluid sphere ($r = 0$), and at the Schwarzschild coordinate singularity at $r_S = 2GM$ - above the center of the sphere but beneath the internal radius of the incompressible fluid. Both irregularities were perceived as troublesome by contemporaries, however, the Schwarzschild singularity has historically been assessed as the major problem. Coordinate transformations of the type of eq. (2) to eliminate the unsteadiness at the Schwarzschild surface have been under development, yet their significance was not fully clarified until the work of Lemaitre (1932); but various other considerations of how to handle with the prediction of irregularities in the metric field were brought forward instead. The central $r = 0$ singularity has likely not been considered as a threat to General Relativity for the reason that it already occurred in the gravitational potential $\phi(r) = -\frac{-GMm}{r}$ between two gravitating point masses M and m in Newtonian gravity. The Schwarzschild singularity, however, was novel and predicted to occur in the deep interior of stars that soon were modelled by Schwarzschild's ideal fluid ansatz: for instance, the Schwarzschild radius of the Sun amounts to roughly

[h] The critical matter concentration threshold is obtained from applying the condition $\cos\chi_a = \frac{1}{3}$ to the externally measured radius $P_a = \sqrt{\frac{3}{\varkappa\rho_0}}\sin\chi_a$, from which follows $P_a = \alpha$ for a point mass and $P_a = \frac{9}{8}\alpha$ for an incompressible fluid sphere. $\alpha/2k^2$ is the gravitational mass.

[i] Translation from the German original into English by the author K. M.

3 km, far below the Sun's radius of about 0.7 million km. Eddington called the Schwarzschild surface the "*magic circle*", and conjectured that no particles inside a star may penetrate this "*impassible*"[2] barrier. Reason is that, as Droste remarked in Ref. 21, the penetration would take an infinitely long time ($g_{tt} \to 0$), or as Einstein put it, "*a clock kept at this place would go at the rate zero*"[23] but nothing could develop without time, according to this line of reasoning.

Observation of stars was at that time period based solely on their surface properties[j], and traced on the Hertzsprung-Russell diagram. Since the prediction of the Schwarzschild singularity thereby escaped any empirical test, the prevailing logical positivist attitude to science, which assumed that any empirically unverifiable statement is meaningless, is likely to have fostered a less concerned view of the Schwarzschild singularity: no stars had been known to have a physical radius smaller than $2GM$, thus the Schwarzschild singularity appeared tolerable so long as it did not produce any falsifiable predictions. Nevertheless, during the Paris conference (1922), Hadamard contemplated the possibility of the Schwarzschild surface surpassing the physical radius of a star. Einstein conceived this scenario as a threat to the theory of General Relativity, and aimed to disprove the possibility of the "Hadamard catastrophe" on physical grounds.

The innermost stable circular orbit. Einstein was guided by an understanding of Mach's principle as implying that the metric field is determined by its matter-energy content, for "*inertia originates in a kind of interaction between bodies*".[24] Guided by Mach's principle, he interpreted a singularity in the gravitational field as an indication of a pathological matter state that gives rise to it. Hence, he aimed to prove that while stellar matter is source of the gravitational field, it is impossible to accumulate matter neither at their center of mass at $r = 0$, nor at the Schwarzschild surface $r = r_S$, where the singularities were supposed to arise. Then -according to his line of reasoning- irregularities in the metric field are unphysical, so long as they are not occupied by matter, which originates the properties of the gravitational field. In his 1939 paper, Einstein's goal was to demonstrate that this holds true in an allegedly more realistic model of stellar matter than Schwarzschild's perfect fluid ansatz. He starts the paper with an expansion of the argument brought forward by Schwarzschild himself, pointing at the inadequacy of incompressible fluid assumption:

> "*The concept of an incompressible liquid is not compatible with relativity theory as elastic waves would have to travel with infinite velocity. It would be necessary, therefore, to introduce a compressible liquid whose equation of state excludes the possibility of sound signals with a speed in excess of*

[j] Asteroseismology, the study of stellar interior structure through their global oscillation modes, which are excited in the interior and induce structural imprints onto photometric observables, had not yet been developed at that time.

> *the velocity of light. But the treatment of any such problem would be quite involved; besides, the choice of such an equation of state would be arbitrary within wide limits, and one could not be sure that thereby no assumptions have been made which contain physical impossibilities.*"[23]

Instead, Einstein proposes another model: a spherically symmetric self-gravitating many-body system composed of non-interacting point particles of equal unit mass. For this system, Einstein calculates the interior gravitational field and equations of motion, and finds the innermost stable circular orbit (ISCO) to lie above the Schwarzschild radius in GR, in contrast to the treatment of the same many-body system in Newtonian gravity, which does not yield any lower bound on the radius of the ISCO. Orbits of a radius tighter than the Schwarzschild radius, as he finds, require orbital velocities that exceed the speed of light, which is prohibited by the principles of relativity theory. From there, he concludes that the irregularities in the metric field at $r = r_S$ and at $r = 0$ are physically irrelevant, because these regions do not get populated by particles in the self-gravitating many-body system.

Einstein's calculations were correct and insightful in their own right, however he draw false conclusions from them. With his background premise that all test particle orbits always remain stable, he excluded possibility of unstable orbits, such as an inspiral. A more cautious conclusion would have been that there are no *stable* particle orbits within a certain distance away from the Schwarzschild radius. A spiral-like particle trajectory, of orbital velocity smaller than the speed of light yet beneath the innermost stable orbital radius, is not impeded from arising by Einstein's calculation: Einstein's calculation shows that an orbit radius lower than r_S cannot be circularly stable.

The Einstein-Rosen bridge. Einstein was even ready to sacrifice the original version of the gravitational field equations for the sake of doing away gravitational singularities in the Schwarzschild metric. At the same time, he was opportunist[25] about turning the prediction of field singuilarities into a solution to the problem of particle representation and of particle motion in General Relativity. With regard to the latter problem, he saw the logical independence of the geodesic law from the field equations as a weakness of GR. One of his approaches to a remedy was to derive the geodesic law from application of the covariant conservation law $\nabla_\nu T^{\mu\nu} = 0$ to the Einstein Field Equations (EFE) at the limiting case of matter-free space ($T^{\mu\nu} = 0$). From there would follow that, "*[i]f one assumes that matter is arranged in narrow 'world tubes', one obtains from this by an elementary consideration the theorem that the axes of those 'world tubes' are geodesic lines (in the absence of electromagnetic fields). This means: the law of motion is a consequence of the field law.*".[26] With regard to the former problem, Einstein assessed the representation of matter by the stress-energy tensor as phenomenological approximation, as a crude substitute of known (quantum) properties of matter. Instead, singularities in the

gravitational field, seemingly problematic at first, opened up a novel approach to resolve another problem. His proposal was the representation of elementary particles by pole singularities in an empty gravitational field:

> "*All attempts to represent matter by an energy-momentum tensor are unsatisfactory and we wish to free our theory from any particular choice of such a tensor. Therefore we shall deal here only with gravitational equations in empty space, and matter will be represented by singularities of the field.*"[27]

In this approach unifying particle representation and motion, particles in GR are represented by localized pole singularities in the metric fields $g_{\mu\nu}$, which outside the singularities are regular elsewhere and satisfy the source-free ($T_{\mu\nu} = 0$) EFE, while particle geodesics are represented as displacements of pole singularities in and by the gravitational field obeying the source-free EFE. This approach was a stepstone toward a unified field theory Einstein was questing for, yet Einstein presumed that the total field (obtained from what he refers to as the "*completed field equations*"), unifying the gravitational field and the matter field, would eliminate singularities:

> "*[...] one will have to say that the field of a material particle may the less be viewed as a pure gravitational field the closer one comes to the position of the particle. If one had the field equation of the total field, one would be compelled to demand that the particle themselves would everywhere be describable as singularity free solutions of the completed field-equations.*"[28]

The prediction of singularities in solutions to the EFE fostered his view that GR is a preliminary, not the final field theory. The belief in the singularity representation of particles was further shaken Silberstein's argument[29] that, due to the existence of a *static* axisymmetric solution to the field equations representing two pole singularities, either the field equations are wrong, or the problem of motion cannot be treated with it, or particles cannot be represented as singularities. Reason is that the two particles so represented are, in Silberstein's construction, immobile and not accelerated in each other's gravitational field. Influenced by Silberstein's argument, in Einstein's 1935 paper with his student Rosen,[30] the authors present a formalism that casts the representation of a particle from the point mass singularity representation at the origin of the Schwarzschild metric onto a non-singular particle representation obtained from a topological bridge construction connecting two asymptotically flat regions of spacetime. To get there, Einstein and Rosen proceed by two essential steps. First, they modify the source-free EFE by transforming the Ricci tensor (which equals $R_{\mu\nu} = R^{\lambda}_{\mu\nu\lambda} = g^{\lambda\rho}R_{\rho\mu\nu\lambda} = 0$ in the source-free field) to the tensor density

$$R_{\mu\nu} \rightarrow R^{*}_{\mu\nu} = g^{2}R_{\mu\nu} \tag{7}$$

where g is the determinant of the metric field $g_{\mu\nu}$. The effect it had in their study of the flat Minkowski metric in Rindler coordinates is that the irregularity condition $g = 0$, since the new field equations have no denominators in g and do not result in 'divide by zero' divergences. Hence, Einstein & Rosen's move was to make the unsteadiness singularity condition $det(g_{\mu\nu}) = 0$ itself irrelevant, by the mutilation of the source-free field equations. Second, Einstein & Rosen perform a coordinate transformation, $u^2 = r - 2GM$, which shifts the Schwarzschild singularity down to the origin of the coordinate system, thereby transforming away the entire central region $r \in [0, 2GM[$ and, therewith, the central singularity. They interpret the line element ds^2 resulting from the spherically symmetric solution to the mutilated field equations as describing a spacetime with two congruent sheets (at $u < 0$, and at $u > 0$) cross-connected by a "bridge" at $u = 0$ (hence $r = 2GM$). Despite that g vanishes at the shifted $u = 0$ origin, the unsteadiness singularity condition is invalidated by the mutilated EFE for an empty gravitational field:

> "*The whole field consists of two equal halves, separated by the surface of symmetry* $x_1 = 0$*, such that for the corresponding points* (x_1, x_2, x_3, x_4) *and* $(-x_1, x_2, x_3, x_4)$ *the* g_{ik} *are equal. As a result we find that, although we are permitting the determinant* g *to take the value* 0 *(for* $x_1 = 0$*), no change of sign of* g *and in general no change in the 'inertial index' of the quadratic form occurs.*"[30]

Electrically neutral[k] particles are henceforth described by topological ripples in the singularity-free solution of the new source-free field equations, for which the problem of particle representation and motion coincides. While the topological bridge construction extends the spacetime region from $u > 0$ onto another $u < 0$ (and vice versa), it has later shown to be non-traversible.[31] What remains problematic in the Einstein-Rosen argument is the assessment of whether a spacetime is singular or not in coordinates in which the Schwarzschild metric is not maximally extended. The maximally extended Schwarzschild metric is given by the Kruskal-Szekeres spacetime,[32] which analogously allows for a topological bridge construction connecting two spherically symmetric halves. However the crucial difference to the Einstein-Rosen calculation is that, in the Kruskal-Szekeres spacetime, the symmetric halves are glued together at the $r = 0$ line. In consequence, gravitational singularity formation is not avoided, since the Kretschmann scalar diverges at $r = 0$ in the maximally extended Kruskal-Szekeres spacetime.

[k]The authors move on to consider the case of a charged particle. To account for the electromagnetic charge, they solve the mutilated field equations with a $T^{\mu\nu}$ source term that represents the Maxwell electromagnetic field. Here they introduce a second modification to the EFE, consisting in the change of sign (from positive to negative) of the stress-energy tensor $T^{\mu\nu}$ on the right-hand side of the EFE for the sake of again obtaining the topological bridge as solution to the metric field from the unified treatment of gravitation and electromagnetism. The change of sign, on the other hand, forces Einstein & Rosen to concede the possibility of negative stress-energy.[25]

2.2. *Chandrasekhar's mass limit vs. Eddington's equilibrium hypothesis*

In 1926 Eddington published seminal work[33] on the theory of internal structure, energy generation, radiation transfer and evolution of stars, which remained the primary source of reference for generations of astrophysicists (although the process of nuclear fusion as the dominant supply source of stellar inner energy was not clarified until work of Bethe & Bloch (1939)). Henceforth, the scientific community was equipped with more realistic models of stellar matter, which allowed to address the *astrophysical* viability of the prediction of gravitational singularities in stars modelled by the Schwarzschild ideal hydrodynamics ansatz. The 'standard model' of stellar structure assumed contributions to the Equation of State (EOS) $P = P(\rho, T)$ from classical ideal gas pressure $P \propto \rho T$ and from the Stefan-Boltzmann law of black body radiation pressure $P \propto T^4$ as the main pressure sources that counterbalance gravitational contraction of the star and maintain HE of the perfect fluid in its interior. This 'standard model' was an adequate approximation for most types of observed stars, but not for the faint White Dwarf stars. Based on comparison of observed stellar bolometric luminosity and total mass tuples, Milne (1930) suggested that in order for a steady equilibrium state to always hold, the classical ideal gas law must break down beyond a critical core luminosity L_c, at which he argued that the matter configuration in the White Dwarf star must condense to a quantum degenerate gas.[34]

Breakdown of the (polytropic) Equation of State. Chandrasekhar's achievement consisted in the calculation of an upper mass limit[35,36] for mechanical stability of an electron degenerate White Dwarf star, beyond which the Pauli pressure of electrons is not sufficent to counterbalance collapse of the star under the weight of the nuclei it is composed of. In his calculation, Chandrasekhar models the electrons by a quantum ideal Fermi gas, which respect the Pauli Exclusion Principle (a maximum of two electrons, with anti-aligned spins in the 'up' and 'down' states, are allowed to occupy the same classical phase space cell) and whose energy levels are occupied up to the Fermi energy maximum according to Fermi-Dirac quantum statistics. The Pauli degeneracy pressure relates to electron density ρ_e by the polytropic EOS law $P(r) = K\rho(r)^\gamma$, which is independent of temperature, and where the adiabatic index equals $\gamma = 5/3$ (non-relativistic degeneracy) or $\gamma = 4/3$ (special relativistic degeneracy). The electron density itself is dependent on nuclear composition and density of the White Dwarf, and the parameter K takes this into account. Chandrasekhar works with a simple White Dwarf model composed solely of protons and electrons. In a Newtonian gravity treatment, Chandrasekhar proceeds by imposing the HE condition

$$\frac{dP(r)}{dr} = -\frac{Gm(r)}{r^2}\rho(r) \tag{8}$$

where $m(r)$ is the shell mass up to radius r, obtained from the volume integral over the total density profile $\rho(r)$. He further assumes that the density distribution peaks in the center ($r = 0$) of the White Dwarf. From there he follows that there is an upper limit to total mass M, for any given density gradient $\rho(r)$, at which electron degeneracy pressure is still sufficient to maintain HE. As the star contracts under its own gravity, electrons need to speed up in their motion in order to retain the necessary phase space volume that is required to accomodate all of the electron states in accord with the Pauli principle. He finds that, as *all* the electrons inside the White Dwarf attain relativistic degeneracy, the polytropic index (and thereby also the pressure) decreases, and at a critical Chandrasekhar mass (which, in general, depends on nuclear composition of the star, and for which the solar mass unit $\odot$ is commonly used) the internal radius of the White Dwarf tends to zero:

> "*We are bound to assume therefore that a state must come beyond which the equation of state (...) is not valid, for otherwise we are led to the physically inconceivable result that for* $M = 0.92 \bigodot \beta^{-\frac{3}{2}}, r_1 = 0$, *and* $\rho = \infty$."[37]

Chandrasekhar's fluid ansatz was different from Schwarzschild's in that Schwarzschild calculated the resulting pressure required to sustain HE for any incompressible fluid of given density and radius, while Chandrasekhar instead assumed a relativistic electron degeneracy pressure source to calculate the maximum mass that still maintains the fluid's HE, as function of a specified matter density gradient that peaks in the center. However both the authors arrive at the compatibility of their solution equations with the formation of a singular density ($\rho \to \infty$) point mass, and both suggest to dismiss this conclusion under sacrifice of the scope of validity of their respective solution equations: Schwarzschild's turn was to suggest that the assumption of the incompressible fluid breaks down, while Chandrasekhar's turn instead was to argue that it is not the general framework of the perfect fluid ansatz itself but the polytropic EOS employed therein what breaks down[1]. The Chandrasekhar mass limit improved an earlier upper mass limit estimate

[1]Apart from dismissing the scope of validity of the polytropic EOS, another turn is to reject the presumption that the HE condition continues to be valid as the Chandrasekhar mass is approached. Neither Schwarzschild nor Chandrasekhar question the appropriateness of the HE condition in the aforementioned works *before* the critical mass concentration limit is reached. To anticipate, as is known today from a more realistic treatment of matter in electron degenerate stellar cores, nuclear and particle interactions may trigger hydrodynamic instabilities and the energy release that power explosions as the Chandrasekhar mass is approached. Thermonuclear reactions inside a White Dwarf, composed of -for example- a degenerate Carbon-Oxygen core that is surrounded by an outer shell of mainly Helium ions, under certain yet not well understood conditions[38] (one possible progenitor mechanism is the accretion of hot matter onto the White Dwarf from a companion star) ignite a deflagration or detonation before the Chandrasekhar mass limit is attained, which unbinds (thermonuclear runaway energy release from Carbon fusion is one of the possible explosion mechanisms) the star in a Type 1a Supernova, and leaves no remnant behind. In more massive stars, an (effective) Chandrasekhar mass limit indeed sets the condition for onset of stellar core collapse (CC), onward of which the HE assumption becomes an inappropriate constraint on the physics: violent Neutron Star formation is one of the outcomes of CC, after -according to current

by Stoner (1930) who assumed a constant density fluid. With the theoretical model of gravitational implosion ($r_1 \to 0$) of a sufficiently massive White Dwarf star, he demonstrated that (Newtonian) gravitational singularity formation is not merely a mathematical curiosity but a possible outcome of stellar evolution that connects to stellar progenitor models.

The final equilibrium conjecture. Driven by views of a philosophy of science which exclude the possibility of gravitational implosion, Eddington vehemently dismissed Chandrasekhar's mathematically rigorous calculation of an upper mass limit for mechanical stability of a White Dwarf star. During the meeting of the astronomical society, he expressed concerns about the relativistic degeneracy formula deployed by Chandrasekhar, suggesting that quantum degeneracy is lifted when relativistic effects become important:

> "*The formula is based on a combination of relativity mechanics and non-relativity quantum theory, and I do not regard the offspring of such a union as born in lawful wedlock (...) There is no such thing as relativistic degeneracy!*"[39]

Instead, he conjectured that when the nuclear energy supply is exhausted, the star reaches a final stable equilibrium state at which radiation pressure compensates further gravitational contraction:

> "*The star has to go on radiating and radiating and contracting and contracting until, I suppose, it gets down to a few km radius, when gravity becomes strong enough to hold in the radiation, and the star can at last find peace.*"[39]

His argument was heuristic and not grounded upon an elaborated theoretical final equilibrium model, but it was influential enough to prevent Chandrasekhar's work from receiving a wider attention.

2.3. *Tolman-Oppenheimer-Volkoff mass limit vs. unexplored Equation of State effects*

(More) compact stars. The discovery of the neutron[40] in 1932 opened up new directions in nuclear stellar astrophysics. But even prior to its discovery, Landau

'standard' CC Supernova models- a neutrino-driven convection-enhanced explosion has ejected a significant fraction of mass from the collapsing core. The explosive mass ejection allows the stellar post-collapse remnant find a new HE state at ultra-dense matter conditions, which -in the simplest treatment- is again modelled by a polytropic Equation of State: HE is now sustained by neutron degeneracy pressure of a quantum ideal gas composed of neutrons.

presented a model[m] of a more compact stellar core, taking form of a "*gigantic nucleus*",[41] composed of a stable matter configuration at which the protons and electrons still co-exist at densities even greater than the limiting $\rho_c \propto 10^{12} \frac{g}{cm^3}$ assumed in the original Chandrasekhar mass White Dwarf. While Landau did not explicitly invoke a neutron composition in his stellar core model, he anticipated the idea that stable matter configurations at even higher densities than the White Dwarf do exist, and still are adequately approximated by a polytropic EOS, taking degeneracy pressure into account. Few years later, in 1934 the astronomers Baade and Zwicky suggested the explosive transformation of an ordinary star into a Neutron Star as an explanation of observations of supernova transients.

> "*If super-novae are giant analogues to ordinary novae, we may expect that ionized gas shells are expelled from them at great speeds. If this assumption is correct, part of the cosmic rays should consist of protons and heavier ions. [...] We have tentatively suggested that the super-nova process represents the transition of an ordinary star into a neutron star. If neutrons are produced on the surface of an ordinary star they will 'rain' down towards the center if we assume that the light pressure on neutrons is practically zero. This view explains the speed of the star's transformation into a neutron star.*"[42]

The details of the nuclear physics involved therein, in particular the transition of the protons, bounded together by the strong nuclear force, into neutrons by virtue of undergoing Electron Capture, were developed in subsequent years by Hund (1936) and by Gamow (1937).[43] Because of the half-integer spin of the neutrons, Pauli pressure of the neutron ideal Fermi gas, rather than of the electron gas, is responsible for maintaining stability of the compact star, withstanding further gravitational contraction. Oppenheimer & Serber (1938) re-estimated the upper mass limit for a stable degenerate neutron core modelled by a polytropic EOS, but corrected the result of Landau, which posed too tight constraints on nuclear binding energy.[44]

Unexplored EOS effects. A treatment of degenerate neutron cores in General Relativity followed soon hereafter: it was based on Tolman's solution ansatz to the interior Schwarzschild field of a spherically symmetric static matter distribution[45,46]:

$$ds^2 = e^v dt^2 - \frac{1}{1 - \frac{2Gm(r)}{r}} dr^2 + r^2 g_\Omega \tag{10}$$

[m] He arrives at the important formula

$$M_0 = \frac{3.1}{m^2} \left(\frac{\hbar c}{G} \right)^{3/2} \tag{9}$$

where M_0 is the limiting mass that is sufficient to maintain the (Newtonian) HE, and the parameter m is the mass of a nuclear ion per one electron. For a degenerate White Dwarf core, $m \simeq 2m_p$ where m_p is the proton rest mass, and from there follows the well-known $M_0 \simeq 1.44 M_\odot$ Chandrasekhar limit.

where $m = m(r) = \int_0^r dr' 4\pi r'^2 \rho(r')$ is the volume integral over energy density up to the radial coordinate r, and where the coefficient $v = v(r)$ obtained from the fluid's EOS. Oppenheimer & Volkoff (1939) adopted this ansatz for their calculation of the gravitational field inside neutron cores,[47] which they assumed to have density $\rho(r)$, isotropic pressure $P(r)$, be at rest ($u^\mu = 0$) and under the absence of mechanical stresses. Under these assumptions, the stress-energy tensor of the perfect fluid

$$T^{\mu\nu} = \left(\rho(r) + \frac{P(r)}{c^2} u^\mu u^\nu - P(r) g^{\mu\nu} \right) \tag{11}$$

simplifies, with $T^1_1 = T^2_2 = T^3_3 = -P$ and $T^4_4 = \rho$ remaining as the only non-vanishing diagonal components. Plugging them and Tolman's metric ansatz into the EFE $R_{\mu\nu} - \frac{1}{2} R g_{\mu\nu} = \frac{8\pi G}{c^4} T_{\mu\nu}$, they derive a general relativistic HR condition, which -in a modern reformulation of the solution equations- reads

$$\frac{dP(r)}{dr} = -\frac{Gm(r)}{r^2} \rho(r) \left(1 + \frac{P(r)}{\rho(r) c^2} \right) \left(1 + \frac{4\pi r^3 P(r)}{m(r) c^2} \right) \left(1 - \frac{2Gm(r)}{rc^2} \right)^{-1}. \tag{12}$$

In the general relativistic HE, both the stress-energy field *and* the gravitational field are stationary. The solution to the TOV equation (12) requires the supply of an EOS $P = P(\rho, T)$, which reduces to $P = P(\rho)$ if temperature-independent (as in the polytropic case), and which coincides with Schwarzschild's 1916 solution to the interior field if the constant density assumption $\rho(r) = \rho_0$ is made. In their calculation of the upper mass limit to general relativistic stability, Oppenheimer & Volkoff model the neutron core by a variant of a more realistic polytropic EOS than Landau's, which however only takes into account Fermi degeneracy pressure of the neutron gas, and neglects contributions to the EOS from thermal energy and internal particle interaction forces. Under these assumptions, they derive a general relativistic upper mass limit $M_{TOV} \leq \frac{3}{4} M_\odot$. At the same time, they comment on solutions to the field equations for greater core masses:

> "*For masses greater than $\frac{3}{4} M_\odot$ there are no static equilibrium solutions. (...) There would then seem to be only two answers possible to the question of the 'final' behaviour of very massive stars: either the equation of state we have used so far fails to describe the behaviour of highly condensed matter that the conclusions reached above are qualitatively misleading, or the star will contract indefinitely (...) although more and more slowly, never reaching true equilibrium.*"[47]

The Tolman-Oppenheimer-Volkoff mass limit is seen as a first general relativistic (albeit rather coarse, given a simplistic treatment of matter in the neutron core) demarcation between a Neutron Star vs. Black Hole final fate of core collapse. As an alternative to complete gravitational collapse, the authors trace out a similar argument to Chandrasekhar's, namely that the EOS used in their calculation might

become inadequate at more extreme matter conditions[n] and that yet unknown pressure sources (which not necessarily need to arise from fermionic degeneracy pressure) might be responsible for restoring HE of the star. In that case, the TOV condition eq. (12), and resulting mass limit, needs be re-evaluated with a yet unexplored EOS, in place of the polytropic ansatz which accounts for fermionic degeneracy pressure.

3. Oppenheimer-Snyder collapse (1939–1965)

3.1. *Indefinite gravitational contraction*

After Oppenheimer and Volkoff established the upper mass limit for stability of a neutron core in 1939, Oppenheimer and his student Snyder that same year sought for solutions to the EFE for the case that the TOV mass limit is exceeded by polytrope fluid models of mass $M > M_{TOV} = 0.75\,M_{\odot}$, beyond neutron star densities ($\rho_c \propto 10^{15} \frac{g}{cm^3}$). Their result is that they do not find any stable matter states that allow for *stationary* solutions to the field equations for $g_{\mu\nu}$ that would respect the TOV equilibrium condition. Instead, under the idealizing assumption of vanishing pressure $P(r) = 0$, they find an analytical *evolved* solution to the gravitational field, describing gravitational collapse of freely falling matter henceforth simply modelled as dust. They reformulate Tolman's ansatz to the interior Schwarzschild metric (eq. (10)) in a coordinate system that is co-moving ($u^{\mu} = 0$) with the collapsing matter. As result, the stress-energy tensor again takes the simple form of eq. (11), but -given the zero pressure assumption- the only non-vanishing component is the density $T^4_4 = \rho$. The gravitational contraction of the star is continued indefinitely: as the continued spherically symmetric gravitational contraction shrinks the sphere of dust down to asymptotically zero, the central density diverges, local measures of

[n]When taking a leap further ahead into the future, the reliance of compact star models on developments in nuclear and particle physics becomes evident: after the postulation of the subnuclear quark particles[48,49] as constituents of hadronic matter and therefore of nucleons in 1964, Ivanenko & Kurdgelaidze in 1965 constructed a simple Quark Star model.[50] With the discovery of the theoretical description of the constituents of matter at a higher energy scale, a novel model for HE, sustained by degeneracy pressure of the constituent fermions, becomes conceivable. The Quark Star model assumes that the quarks constituting the neutron, bound together by the strong interaction at coupling strength $\alpha_s(k^2)$ that logarithmically decreases with scale, at high enough temperatures undergo a deconfinement phase transition to asymptotic freedom. The deconfinement of quarks justifies application of, once again, the quantum ideal Fermi gas model. The free quarks collectively reach a stable subnuclear HE configuration sustained by degeneracy pressure of the fermionic quark gas. Whether or not Quark Stars exist in nature is an unresolved scientific enquiry, especially in light of the fact that according to more recent, state-of-art models of Neutron Stars, the EOS of their (possibly deconfined and quark degenerate) cores is not well understood.[51]

The lower the mass, the lower does the quark degeneracy pressure need to be in order to maintain HE. Putatively, Quark Stars are therefore physically reasonable mimickers of very *low* mass Black Hole, but not of intermediate mass, massive, and supermassive Black Hole candidates. It is unlikely that the degeneracy pressure from any of the established fermions known in today's Standard Model of elementary particle physics is sufficient for the corresponding exotic compact star to act as supermassive Black Hole mimicker. However, certain models of compact Boson Stars open up new directions for physical speculation.

curvature diverge, and incomplete geodesics form.[o] The admission of the formation of a point mass singularity by the solution equations has been found before in the perfect fluid models of Schwarzschild, Chandrasekhar, Landau and Oppenheimer & Volkoff. What is remarkable[p] about the Oppenheimer & Snyder solution is that, along with the curvature singularity (which is, by virtue of the EFE, consequence of a locally divergent stress-energy field), their calculations also predict geodesic incompleteness.

Non-vanishing pressure and mass loss effects. The Oppenheimer-Snyder type dust collapse model fulfills the conditions for the Raychaudhuri-Komar singularity theorem to apply, which implies formation of an infinite density point mass provided that the Weak Energy Condition (see Sec. (3.3)) holds: the Oppenheimer-Snyder collapse assumes a perfect fluid, which is irrotational, and geodesic (the absence of proper acceleration is consequence of the $P = 0$ assumption). From an infinite density point mass, the EFE imply a *curvature* singularity. Though what is more, the authors affirm their belief in the validity of the solution equations even for the case of non-zero pressure $P \neq 0$:

> "*We believe that the general features of the solution obtained in this way give a valid indication even for the case that the pressure is not zero, provided that the mass is great enough to cause collapse (...) Of course, actual stars would collapse more slowly than the example which we studied analytically because of the effect of the pressure of the matter, of radiation, and of rotation.*"[52]

At the same time, they enumerate a number of physical mechanisms that could prevent a star from surpassing the TOV mass limit, after all of its thermonuclear internal energy resources have been exhausted:

(1) the fission of the star into fragments by its rotation,

[o] Setting the proper time τ of a local observer co-moving with the collapsing matter of the outermost dust shell in relation with the coordinate time measured by a distant observer t outside the collapsing star, and taking the asymptotic limit $t \to \infty$, they find that proper time of a time-like geodesic converges to a finite $\tau \to \tau_0$. As the collapsing star shrinks beneath its Schwarzschild radius, time-like geodesics become space-like. The authors calculate the asymptotic space-like configuration of the gravitational field inside the collapsing star: the temporal component $g_{tt} \to 0$ vanishes while the radial component g^{rr} reaches a finite configuration in the interior $r < r_S$ except at $r = 0$ where it becomes infinite. In addition, a coordinate singularity develops at $r = r_S$.

[p] The authors also anticipate the idea that the two-sphere $r = r_S$ constitutes an event horizon, preventing an escape from the collapsing star and isolating it from any causal interaction with the exterior:

> "*After this time τ_0 an observer comoving with the matter would not be able to send a light signal from the star; the cone within which a signal can escape has closed entirely.*"[52]

(2) photon radiation pressure blowing off outer mass layers,
(3) significant enough mass radiation.

From the perspective of modern astrophysical stellar evolution models of the late pre-collapse evolutionary stages, the above mentioned effects are unlikely to be strong enough to be a general argument preventing implosion of a physically realistic massive core.[q]

3.2. *The Landau-Wheeler arguments, and Boson Stars*

Landau pointed out in his 1932 and 1938 papers that a compression of fermions, over course of stellar gravitational collapse, to a point mass, with all fermions occupying the same phase space cell, leads to violation of fermionic quantum statistics,[41,56] which prohibits occupation of the same quantum state by more than one fermion. The formation of a point mass singularity is further complicated by other quantum principles. In particular, the Heisenberg uncertainty principle, according to which position and momentum of a particle cannot both be precisely constraint at the same time. Energy compactness considerations, advocated by Wheeler, according to which a quantum particle of given rest-mass energy is not allowed to localize at scales smaller than its Compton wavelength in order to be well-defined. Wheeler confronted Oppenheimer at the Solvay Conference (1958) to argue on heuristic grounds that the collapsing (fermionic) nuclear matter must dissolve into electromagnetic, gravitational and/or neutrino radiation.[57] In a way, his opposition to Oppenheimer's result was akin to Eddington's to Chandrasekhar's work, in that Wheeler took up Eddington's idea that radiation becomes held in the star, which though still maintains its final equilibrium. But Wheeler went further with an elaborated model of a *Geon* as a HE candidate. In 1955, a decade before the stationary

[q](1): According to more recent computer simulations of rotating core collapse that deploy a polytrope EOS,[53] the infalling matter is indeed fragmented into an inner core contracting subsonically and an outer core contracting supersonically. The centrifugal force has the effect of deforming the inner core, and reducing the available gravitational energy to 'push' the outer core into an explosion. Rotation therefore has impact on the fate of the collapsing core regarding whether it explodes or not, but is not an implosion preventing mechanism that generalizes. (2): The high energy photon radiation in the hot stellar core leads to photo-disintegration of heavy nuclear ions (mostly iron group elements), which a more realistic massive core is composed of. Therefore, the photo-disintegration facilitates rather than prevents gravitational collapse, for it occurs at the price of taking away internal energy from the star: thermal radiation pressure contributes to the total pressure that maintains HE, and photo-disintegration has the overall effect of reducing it.[54] (3): Stellar winds in late phase massive star evolution do significantly contribute to mass loss, however the mass radiation mostly takes away mass from the envelope rather than from the core of the star, which -due to its greater compactness- is stronger bound gravitationally. Mass ejection from the core is strong enough only in the case of a CC Supernova explosion, signalling the violent birth of a proto-Neutron Star. However, a successful launch of an explosion is only one of the possible outcomes of stellar CC, along with a Failed Supernova, a Weak Supernova that precedes Black Hole formation by fallback of ejected matter onto the proto-Neuton Star, and the direct quiescent Black Hole formation.[55]

Newman-Kerr electrovacuum solution was found, Wheeler presented a solution to the EFE describing a spherically symmetric confined classical radiation field. His idea was that radiation is trapped in form of standing waves in closed circular toroid tracks of radius of the Geon, and collectively arranges to form stable macroscopic objects.[58] These Geon configurations were supposed to consist of either of trapped electromagnetic waves or of trapped gravitational waves, held together by their own self-gravity in a stable equilibrium state. Since their reduced wavelength is negligibly small compared to the radius, the Geon decay rate is negligible over long time scales. By proposing a non-singular bosonic HE alternative to gravitational implosion, Wheeler further elaborated not only Eddington's but also Landau's argument. Though the transition of fermionic mass-energy to bosonic states in a collapsing star still remained a conjecture, without a specified generic transition mechanism. Alas, his model -as well as variants thereof- turned out to be unstable: a small equilibrium perturbation to the confined radiation field leads to onset of its implosion.[r]

Following a different approach in line with Wheeler's *Geometrodynamics* research program, Wheeler together with his student Fuller returned to the idea of a non-singular Einstein-Rosen bridge connecting two symmetrical regions of an empty spacetime, and studied Wormhole solutions in the maximally extended Kruskal-Szekeres metric, with an introduced minimum proper circumference at the connecting "throat" in order to obtain a singularity-free metric.[31] But it was found that these suffer from qualitatively the same problem as Geon models, namely that Wormholes in 4-dimensional, general relativistic spacetime are unstable against equilibrium perturbations in a dynamic problem (which results in shrinkage of circumference of the throat down to zero, and divergence of curvature invariants after finite proper time), unless even higher-dimensional space-time or quantum theoretical considerations are taken into account that stabilize the topological bridge.

[r]However, when a complex scalar field φ is considered instead of the electromagnetic field, the equation of motion for the complex scalar field (the Klein-Gordon equation) admits stable geon-like soliton solutions, stabilizing as a Boson Star. Their gravitational field is sourced by the self-gravity of the bosonic waves, which are dispersed in accordan with the Klein-Gordon equation, satisfying the laws of Bose-Einstein quantum statistics: bosonic particles of mass μ confined within an object of size $2R$ possess a proper velocity $v \propto (2R\mu)^{-1}$. It is the Heisenberg uncertainty pressure of the bosons which provides the pressure (along with a self-interaction term, which adds either a positive or a negative contribution to pressure, depending on the nature of the self-scattering potential $V(\varphi)$) to counterbalance contraction and maintain HE. However, given a limitation by the finite internal radius, and thereby the proper velocity of the Bosons, there is a maximum mass to stability of a Boson Star, $M_{BS} \propto \frac{m_P^2}{\mu}$ (whose precise value is determined from specific boson star models), beyond which the Heisenberg uncertainty pressure is insufficient to withstand gravitational collapse (m_P is the Planck mass).[59] It therefore seems not implausible that Boson Stars, even if they exist, are only an intermediate stable configuration state, before gravitational collapse of the compact Boson Star occurs if it has become sufficiently massive.

3.3. *The Khalatnikov-Lifshitz asymmetry argument, and Penrose's 1965 theorem*

The Oppenheimer & Snyder paper convinced Landau about the reality of complete gravitational collapse of matter, but not of the irregularities in the metric field by the formation of singularities (referring to all three notions defined in Sec. 1). As one of the leading figures of the Soviet school assessed the prediction of gravitational singularities in collapsing stars as well as in Early Universe Cosmology to be the major unsolved problem of theoretical physics, his judgement would shape the thinking of a generation of Soviet theorists. The Landau school accepted the reality of gravitational collapse sooner than the Wheeler school, and would endow it with the name "Frozen Star", grounded upon effects at the Schwarzschild boundary, apparent to an external observer, rather than interior singularity hallmarks.[s] Doubting singularity formation as physically viable, Khalatnikov and Lifshitz in the early 60s advocated that in any physically realistic stellar gravitational collapse scenario, the condition of spherical symmetry, inherent in the Schwarzschild metric, would be violated.[60] In realistic asymmetric collapse, they argued that nonlinearity effects would dominate the interaction between gravitational field and matter, resulting in chaotic dynamics and impeding formation of the central singularity. Instead, they interpreted the central singularity as an artifact prediction that arises from the imposed spherical symmetry condition in the Oppenheimer-Snyder collapse.

Penrose's work on the singularity theorem[61] historically was motivated as a counter to the Khalatnikov-Lifshitz argument. The theorem states that, provided that a set of conditions are fulfilled, the production of geodesic incompleteness singularities is generic to General Relativity theory, independent of spherical symmetry assumptions:

> *The question has been raised as to whether this singularity is, in fact, simply a property of the high symmetry assumed. The matter collapses radially inwards to the single point at the center, so that a resulting space-time catastrophe there is perhaps not surprising. Could not the presence of perturbations which destroy the spherical symmetry alter the situation drastically? [...] It will be shown that, after a certain critical condition has been unfilled, deviations from spherical symmetry cannot prevent space-time singularities from arising.*[61]

[s] Characteristics of the Frozen Star definition are

- the infinite gravitational redshift of light signals, down to zero, emitted from the Schwarzschild boundary, and
- the illusory coordinate singularity effects that, as measured in coordinate time of a distant external observer, it takes infinitely long for the outermost coontracting stellar surface to collapse under the star's Schwarzschild boundary; as well as the infinite gravitational time delay of a test object asymptotically approaching the Schwarzschild boundary from outside but never reaching it.

Penrose starts off with three premises (geodesic completeness, the weak energy condition, and the causality condition) and shows that they lead to a contradiction, provided that a closed future-directed trapping surface, which is not necessarily spherically symmetric, has formed. The resolution of the contradiction requires that one of the premises is refuted. If one holds onto the latter two conditions, then the geodesic completeness assumption needs be rejected. Put differently, the conditions that need be fulfilled in order for the singularity theorem to apply are

- *Weak Energy Condition*: $R_{\mu\nu}\dot{\gamma}^{\mu}\dot{\gamma}^{\nu} \geq 0$, strictly speaking a geometrical condition that demands the convergence of null-like and time-like vector fields γ.[t]
- *Causality Condition*: the spacetime has an initial Cauchy hypersurface, and by global hyperbolicity is time-orientable (no closed null-like or time-like curves).
- *Boundary Condition*: formation of a closed future-trapped surface.

Assuming that the above conditions are satisfied throughout the entire course of stellar gravitational collapse, Penrose's theorem guarantees formation of incomplete null geodesics[u]. For the case of a collapsing star modelled by the Schwarzschild ansatz, the outermost trapped surface forms at $r_b = r_S$ where r_b is the outer boundary of the spherically symmetric collapsing star. Under which generic conditions a trapping surface forms, and whether it is reasonable to assume that the weak energy and causality conditions apply throughout the entire course of gravitational core collapse, are separate research questions that require further investigation, going beyond the scope of this work.

The geodesic incompleteness singularity theorem is independent of the EFE. Therefore, it applies to any theory of gravity, e.g. $f(R)$ theories, formulated using the framework of Lorentzian geometry, that satisfies the stated causality, energy and boundary conditions. The Penrose theorem does not state 'where' in space-time the incomplete geodesics locally form. Moreover, the theorem makes no statement about local curvature divergence. The lack of a physical characterization of geodesic incompleteness formation is by some (e.g. Landau & Lifschitz in Ref. 62) seen as weakness of the theorem - the theorem does not exemplify the reasons for which the geodesic incompleteness occurs: whether or not the path inextendibility is due to

[t] In GR, the Ricci tensor $R_{\mu\nu}$ is related to $T_{\mu\nu}$ by the EFE, which gives the geometrical condition a conceptual interpretation in terms of energy related physical quantities.

[u] A key tool used in the formulation and proof of the singularity theorems is the focusing effect of the Raychaudhuri equation. The equation describes the divergence behaviour of a congruence family of geodesics. The divergence of a congruence is defined as the derivative of the logarithm of the determinant of the congruence volume. Raychaudhuri's equation then describes the evolution of geodesic congruences. The closed trapping surface condition implies that light rays emitted in opposite directions orthogonal to a closed space-like 2-sphere converge. Null geodesics include the entire boundary of the proper future: when they converge from opposite sides, there is no more future boundary. The congruence volume of parallel null geodesics reaches zero within finite affine length. Consequence is the generic prediction that the relativistic spacetime $(\mathcal{M}, g)$ is not future null geodesically complete.

curvature divergence, is left open. The latter fact can, however, instead be seen as a strength of the theorem, in that it allows to treat the geodesic incompleteness and infinite curvature singularity notions apart from one another: the Penrose theorem does not need to relate geodesic incompleteness to any pathological mass-energy or curvature state in order to apply.

3.4. *The Planck-Wheeler length, and Markov's curvature bound*

Curvature fluctuations at Planck scale. Together with his students Harrison and Wakano, Wheeler in 1958 mapped out, in a research study that combines theoretical and numerical work, a catalogue of the endpoints of stellar thermonuclear evolution for a wide range of stellar masses.[57] The catalogue played a pivotal role in his later conviction that along with the White Dwarf and Neutron Star compact remnant endpoints of stellar evolution, the complete gravitational collapse as predicted by the Oppenheimer & Snyder model, although it makes crude approximative assumptions, is a possible outcome of evolution of massive stars. Along with exclusion of alternatives to complete gravitational collapse, the decisive role[64] for Wheeler's conviction was played by computer simulations of CC, in particular those of Colgate & White (1966),[63] which adopted more realistic EOS models of stellar matter, and thereby undermined Wheeler's earlier objection that the Oppenheimer-Snyder collapse model is physically unreasonable. Wheeler's updated stance on the issue of the final fate was that mass-energy disappears, as it gets torn into pieces by the divergent tidal forces at the center of mass. The complete gravitational collapse results in a gravitating vacuum ($T_{\mu\nu} = 0$), which he later called "*mass without mass*", or "*disembodied mass*".[65] However, with regard to the prediction of curvature singularity formation as part of the final fate, Wheeler expressed mistrust in GR as the appropriate theory of gravity at smallest scales. His conviction was that the Planck length $\ell_P = \sqrt{\frac{\hbar G}{c^3}}$ is the minimum scale at which space is resolved in an ultimate theory of gravity, and at which he expected space to exhibit "*quantum foam*"[66] of random curvature fluctuations, including microscopic wormholes. Whether or not a gravitational singularity forms over course of unhalted implosion would then be assessed by a successor theory, after the "*fiery marriage*" of quantum theory and gravitation. The important point he raised is that -while he accepted reality of gravitational collapse- the curvature singularity might be an artifact prediction that arises neither because a yet unexplored pressure source has not been taken into account, nor because of idealization, but because the theory of gravity itself breaks down.

Maximal energy density. Aiming at the same goal (the theoretical preclusion of curvature singularity formation) but following a different line of argument, Markov in 1947 first stated the conditions under which there arises an upper limiting bound to curvature,[67] an idea he would explore and elaborate further over the subsequent

decades (see e.g. Refs. 68, 69) His proposal was that a limiting quadratic curvature invariant

$$R_{\mu\nu\lambda\delta}R^{\mu\nu\lambda\delta} \leq \frac{1}{\ell_P^4} \tag{13}$$

is consequence of a maximal density $\rho_q = \frac{c^5}{G^2\hbar} \simeq 10^{94}\frac{g}{cm^3}$ of mass-energy that is permitted to occur in nature. The limiting energy density, a construction from the ratio of the three natural constants c, $\hbar$ and G of special relativity (SR), quantum theory (QT) and gravitation, remains a conjecture. Though he gives a motivation for it, from consideration of the underlying principles of the theories that provide the limiting constraints: from SR, that the propagation velocity of any signal cannot exceed c (a principle held so sacred by Einstein); and from QT, that the action cannot be less than $\hbar$ (a condition which is violated in classical physics). At the same time, Markov highlights that it is the nonlinearity in the differential gravitational field equations coupling stress-energy to measures of curvature, which needs to supply the energy cut-off to avoid UV divergences and the renormalization problem of quantum field theory.[v]

4. Conclusions

The decades spanning in between Schwarzschild's analytical 1916 solution to the EFE and Penrose's 1965 singularity theorem produced a rich pool of thought about the nature of gravitational singularities, and about the viability of their physical realization in stellar gravitational collapse. The examination of the arguments in favour or against realism on singularity formation requires to take into account considerations from differential geometry, stellar astrophysics, and history of science. We have investigated a long list of singularity formation counter-arguments and, while telling the three gravitational singularity notions apart, came to the following conclusions:

- Geodesic incompleteness is an innovative (as it is not available in Newtonian gravity), the most general and a non-local singularity characterization, which is compatible with but does not require divergence in any curvature quantities, and which does not prima facie contradict principles neither of general relativity nor of quantum theory. Prediction of geodesic incompleteness by Penrose's theorem therefore does not indicate breakdown of GR.

[v]As the maximal density limit is reached, he argues that a phase transition of matter-energy into a de Sitter vacuum takes place. The latter conjecture has been be elaborated by Gliner and Sakharov in 1966, with applications to singularity resolution in Cosmology: the negative pressure $P = -\rho < 0$ obeyed by the false vacuum $T_{\mu\nu} = \Lambda g_{\mu\nu}$ introduces a repulsive term into the field equations and violates, by virtue of the EFE with Λ included on the right-hand side, the weak energy condition. With the unclarified nature of Λ, the de Sitter phase transition is a non-singular albeit speculative outcome of gravitational collapse, whose investigation goes beyond the scope of this work.

- An infinite quadratic curvature invariant is not a trustworthy prediction of GR, because it is a local singularity characterization evaluating properties of the gravitational field down at microscopic scales below the Planck length, while GR is a phenomenological theory of gravity. A microscopic theory of gravity theory, perhaps a unified field theory Einstein and Wheeler were questing for, would reconcile the physics of the gravitational field itself with principles of quantum theory. In addition, there are several sub-classes of infinite curvature singularities, which are problematic in their own right.
- Curvature singularity avoidance is achieved in general not by introduction of a yet unexplored speculative EOS which either appropriately describes mass-energy at extreme conditions and restores HE in a collapsing star, or implies a phase transition that introduces a repulsive term by virtue of the EFE (even if there are such remedies, GR would still allow for analytic solutions to EFE with singular curvature, which remains problematic), but by modification of the gravitation theory itself. Markov's bound on the quadratic curvature invariant is consequence of a limiting mass-energy density conjecture, from which it is derived. However, theoretical work has shown that -under certain conditions- curvature singularities form in GR even from a vacuum spacetime, as in the case of colliding gravitational waves, independent of matter. We therefore propose to retain Markov's conclusion (eq. 13) but to reverse the logic: a limiting density of both stress-energy and of gravitational energy is consequence of a bound on the quadratic curvature invariant. The curvature bound needs be introduced from first principle quantization considerations, which GR -as a macroscopic theory- does not itself supply from within the gravity theory.
- Curvature divergence signals the breakdown of Lorentzian geometry, independent of the EFE: the continuous nature of Lorentzian geometry permits gravitational contraction in Oppenheimer-Snyder collapse be continued indefinitely, without that a limiting scale is ever reached. GR does not cure a problem it itself inherits from Newtonian gravity: since in either theory measures of distance are non-quantized, a curvature pathology in GR is permitted to occur in GR for the same reason that allows for infinite force in Newtonian gravity. If quantum theory is not well-defined at scales smaller than the Planck length, it is not evident why GR should be. In addition, it is the lowest scale at which Lorentz symmetry applies. ℓ_P therefore is a natural unit measure for quantization of the quadratic curvature invariant, which can only be achieved by a quantizing tessellation of Lorentzian geometry in units of Planck length and Planck time. Assuming that physics at scales below the Planck scale is meaningless, the curvature bound ($R_{\mu\nu\lambda\delta}R^{\mu\nu\lambda\delta} = \frac{1}{\ell_P^4}$ limit) impedes formation of any energy density singularity in any inertial frame, because it makes space contraction to a point an impossibility.

The Hamilton-Jacobi analysis by Peter Bergmann and Arthur Komar of classical general relativity

D. Salisbury
Physics Department, Austin College,
Sherman, Texas 75090, USA
E-mail: dsalisbury@austincollege.edu
www.austincollege.edu

Peter Bergmann initiated in 1966 an application of Hamilton-Jacobi techniques to general relativity. Little had been done by this time on extending this analysis to gauge theories. He proved that when, as in the case of Einstein's theory, the phase space generator of evolution consisted of a linear combination of constraints, the Hamilton principal function must be independent of spacetime coordinates. Also the Hamilton Jacobi equations that determined this functional of the 3-metric retained their form under phase space functionals that were invariant under the action of the spacetime diffeomorphism group. Komar followed up beginning in 1967 with a series of papers in which he proved that a complete solution of the Hamilton Jacobi equations was determined by a commuting set of diffeomorphism invariants. These invariants thereby labeled equivalence classes of solutions of Einstein's equations under the action of the full four-dimensional diffeomorphism group. Furthermore, this set satisfied canonical commutation relations with another invariant set. The hope and expectation was that these invariants could be promoted to quantum operators in a quantum theory of gravity. This framework will be contrasted with J. A. Wheeler's geometrodynamical program in which the only underlying covariance group is spatial diffeomorphisms. The full spacetime diffeomorphism symmetry is replaced by the notion of 'multi-fingered' time. A related dispute concerning the 'sandwich conjecture' will be discussed, relevant to the functional integral approach to quantum gravity. Two three geometries cannot determine a corresponding four geometry if they lie in distinct four dimensional diffeomorphism equivalence classes.

Keywords: Hamilton-Jacobi equations; geometrodynamics; quantum gravity.

1. Introduction

The following is a brief historical overview of work on a Hamilton-Jacobi approach to general relativity that was undertaken by Peter Bergmann and Arthur Komar in the 1960's and 1970's. A more detailed initial version, discussing both the relation of their research to previous and concurrent approaches, and to later progress, appears in Ref. 1. A further revision and expansion is in progress. The emphasis throughout their investigations was on the full four-dimensional diffeomorphism covariance of Einstein's theory. This lead to a divergence with the geometrodynamical approach of John Wheeler and company where only the spatial covariance is fully respected.

2. Bergmann's initial Hamilton-Jacobi analysis of general relativity

It is not widely recognized that it was Peter Bergmann who pointed out to Peres prior to the publication of his groundbreaking paper in Ref. 2 that his S appearing

as an argument in the four general relativistic constraint equations should be interpreted "as the Hamilton-Jacobi functional for the gravitational field." Of course the following are now identified as the Wheeler-DeWitt equations,

$$\mathcal{H}_\mu \left(g_{ab}, \frac{\delta S}{\delta g_{cd}} \right) = 0, \tag{1}$$

where the $\mathcal{H}_\mu \left(g_{ab}, p^{cd} \right)$ are the secondary constraints in general relativity. Bergmann proved in Ref. 3 that in a theory in which the Hamiltonian is constrained to vanish S could not depend explicitly on the time. The argument applied equally well to spatial dependence, as noted first in Ref. 4. Thus $S = S[g_{ab}(\vec{x})]$. Bergmann also showed that the Hamilton-Jacobi equations were form invariant under canonical transformations generated by diffeomorphism invariants. The fact that the numerical value of S is altered under the action of $\mathcal{H}_0$ presented a puzzle. The question arose whether this could this be inconsistent with the accepted notion of 'frozen time'.

3. Komar's isolation of solution equivalence classes

Komar observed in Ref. 4 that although there were only four Hamilton-Jacobi equations the principal function S delivered $6 \times \infty^3$ expressions for the momenta,

$$p^{ab}(\vec{x}) = \frac{\delta S}{\delta g_{ab}(\vec{x})}, \tag{2}$$

and therefore the $p^{ab}(\vec{x})$ are not uniquely determined. Two additional constraints needed to be imposed, with $A = 1, 2$,

$$\alpha^0_A \left[g_{ab}(\vec{x}), \frac{\delta S}{\delta g_{cd}(\vec{x})} \right] - \alpha_A(\vec{x}) = 0. \tag{3}$$

From the fact that

$$\frac{\delta \alpha^0_A}{\delta g_{ab}} + \frac{\delta \alpha^0_A}{\delta p^{cd}} \frac{\delta^2 S}{\delta g_{cd} \delta g_{ab}} = 0, \tag{4}$$

and similarly for the $\mathcal{H}_\mu$ it follows that

$$\left\{ H_\mu, \alpha^0_A \right\} = \frac{\delta^2 S}{\delta g_{ab} \delta g_{cd}} \left(- \frac{\delta H_\mu}{\delta p^{ab}} \frac{\delta \alpha^0_A}{\delta p^{cd}} + \frac{\delta H_\mu}{\delta p^{cd}} \frac{\delta \alpha^0_A}{\delta p^{ab}} \right) = 0. \tag{5}$$

In other words, the α^0_A must be diffeomorphism invariants (and they must also commute with each other.)

The constant values of $\alpha^0_A \left[g_{ab}(\vec{x}), p^{cd}(\vec{x}) \right]$ identify equivalence classes under the action of the spacetime diffeomorphism group. In Ref. 5 he showed that there existed invariant functionals β^A_0 that were canonically conjugate to the α^0_A. However, as formulated at this stage by Komar, one cannot yet obtain solutions of Einstein's equations by setting $\beta^A(\vec{x}) = \frac{\delta S}{\delta \alpha_A(\vec{x})}$. One still requires a temporal coordinate - like the 'intrinsic' q^0 that appears in the free particle action.

In Ref. 5 he showed that there existed invariant functionals β^A_0 that were canonically conjugate to the α^0_A. However, as formulated at this stage by Komar, one

cannot yet obtain solutions of Einstein's equations by setting $\beta^A(\vec{x}) = \frac{\delta S}{\delta \alpha_A(\vec{x})}$. One still requires a temporal coordinate - like the 'intrinsic' q^0 that appears in the free relativistic particle action, with increment given by

$$dS_p = p_\mu dq^\mu, \tag{6}$$

with constraint $p^2 + m^2 = 0$. This can be compared to vacuum general relativity where the non-vanishing contribution to the increment in the action takes the form

$$dS_{gr} = \int d^3x \, p_{ab} dg^{ab}, \tag{7}$$

with constraints $\mathcal{H}_\mu = 0$.

In the particle case one can choose the 'intrinsic time' $t = q^0$ as the evolution parameter and also solve for p_0 resulting in

$$dS_p = -\left(\vec{p}^2 + m^2\right)^{1/2} dt + p_a dq^a. \tag{8}$$

This yields the complete Hamilton principal function

$$S_p(q^a, t; \alpha^b) = -\left(\vec{\alpha}^2 + m^2\right)^{1/2} t + \alpha_a q^a. \tag{9}$$

The analogue of the gravitational α_0^A in this case is p^a. The analogue of the canonical conjugate β_B^0 would be the reparameterization constant $q^a - p^a q^0/p^0$. The general solution is obtained from

$$\beta^a = \frac{\partial S_p}{\partial \alpha^a}$$

Bergmann and Komar, Ref. 6, had explicitly recognized this type of emergence of intrinsic time evolution. Earlier, Komar in Ref. 7 had proposed that intrinsic curvature-based coordinates could be constructed using Weyl curvature scalars. He and Bergmann in Ref. 8 proved that these scalars depended only on g_{ab} and p^{cd}. The question naturally arise as to why Bergmann and Komar did not proceed with the use of intrinsic coordinates in their Hamilton-Jacobi treatment. A Bergmann quote in Ref. 9 from 1971 is revealing: "Although intrinsic coordinates lead, in principle, to a complete set of observables in general relativity, their defects, of which the most glaring is their deviation from Lorentz coordinates, render this procedure illusory. It appears preferable to retain coordinates that are approximately, or asymptotically Lorentzian and hence not to destroy one's intuition." Thus in spite of prolonged occupation with a Hamiltonian formulation of the the underlying general covariance of general relativity, Bergmann still seemed to have ceded undue importance to the more familiar Poincaré symmetry of conventional field theory.

However, as shown in Ref. 10 it is in principle possible to carry out a canonical change of variable in the non-vanishing increment dS_{GR} to intrinsic spacetime coordinates $x^\mu = X^\mu(g_{ab}, p^{cd})$, analogous to the parameter choice $t = q^0$ in the free relativistic particle model. This is a corrected version of Refs. 11 and 12. Current

work with Kurt Sundermeyer and Jürgen Renn is in preparation. One makes a canonical change of variables such that

$$\begin{aligned} dS_{gr} &= \int d^3x\, p^{ab} dg_{ab} \\ &= \int d^3x \left(\pi_\mu dX^\mu + p^A dg_A + \frac{\delta G}{\delta g_{ab}} dg_{ab} + \frac{\delta G}{\delta g_A} dg_A + \frac{\delta G}{\delta X^\mu} dX^\mu \right). \end{aligned} \tag{10}$$

One must find a generator $G[g_{ab}, X_A, g_B]$ such that $p_{ab} = \frac{\delta G}{\delta g_{ab}}$. Then

$$dS'_{gr} := d(S_{gr} - G) = \int d^3x \left(\pi_\mu dX^\mu + p^A dg_A \right). \tag{11}$$

Next choose the X^μ as intrinsic coordinates, i.e., set $x^\mu = X^\mu$. Finally, one eliminates the canonical conjugates to X^μ, π_ν, by solving the constraints. Then we have the resulting intrinsic Hamilton-Jacobi equation

$$\pi_0 \left[g_A, \frac{\delta S'_{gr}}{\delta g_B}, x^\mu \right] + \frac{\partial S'_{gr}}{\partial x^0} = 0. \tag{12}$$

From the complete solutions $S'_{gr}\,[g_A, x^\mu; \alpha_B]$ one can obtain the full set of physically distinct solutions of Einstein's equations from

$$\beta^A = \frac{\delta S'_{gr}}{\delta \alpha_A}. \tag{13}$$

4. Contrast with geometrodynamics

The contrast of this program with Wheeler's geometrodynamics cannot be overstated. The multifingered time approach assumed that the full four-dimensional diffeomorphism symmetry had been lost. States should be labeled by the $2 \times \infty^3$ diffeomorphism invariants $\alpha_A(\vec{x})$, and not by three-geometries.

The passage of time and top-down causation

Barbara Drossel

Institute of Condensed Matter Physics, Technical University of Darmstadt, Hochschulstr. 6, 64289 Darmstadt, Germany
E-mail: drossel@fkp.tu-darmstadt.de

It is often claimed that the fundamental laws of physics are deterministic and time-symmetric and that therefore our experience of the passage of time is an illusion. This talk will critically discuss these claims and show that they are based on the misconception that the laws of physics are an exact and complete description of nature. I will argue that all supposedly fundamental deterministic and time-symmetric laws have their limitations and are supplemented by stochastic and irreversible elements. In fact, a deterministic description of a system is valid only as long as interactions with the rest of the world can be ignored. The most famous example is the quantum measurement process that occurs when a quantum system interacts with a macroscopic environment such as a measurement apparatus. This environment determines in a top-down way the possible outcomes of the measure- ment and their probabilities. I will argue that more generally the possible events that can occur in a system and their probabilities are the result of top-down influences from the wider context. In this way the microscopic level of a system is causally open to influences from the macroscopic environment. In conclusion, indeterminism and irreversibility are the result of a system being embedded in a wider context.

Keywords: Indeterminism, irreversibility, contextual emergence, top-down causation, nonreductionism

1. Introduction

The success of physics at explaining, calculating and controling processes in nature has led to the widespread belief that the equations of physics describe accurately how the state of a system changes with time under the influence of the various physical forces. Even more, many physicists think that the properties of the fundamental equations of physics are also properties of nature. Since these equations are deterministic, it is concluded that nature also is deterministic, with the time development being completely determined by the initial state and the fundamental laws. Furthermore, these laws are invariant under changing the direction of time. Based on this, many physicists think that the perceived direction of time is merely a consequence of very special initial conditions of the universe, and that all processes in nature could in principle also run backwards in time. Einstein is the most prominent scientist who considered the irreversible passage of time as an illusion since the present contains already the future, as it is fixed by the deterministic laws of physics and the initial conditions.

The implications of this understanding of physics are immense. It follows in particular that our experience of being agents that can act in the "now" and thus bring about future developments is also an illusion. And if everything is fully determined by the laws of physics, this contradicts our experience that our decisions are driven by non-physical causes such as values and logic and purpose.

While many philosophers of science buy the bold claims made by physicists, others are more skeptical. Indeed, there are many reasons to be skeptical. Physics as a science is always an approximate and incomplete description of nature and not a direct image of what goes on in nature. And many physicists not working with supposedly 'fundamental' physics such as quantum physics, but in condensed matter physics or soft matter physics, are aware of these limitations of the basic physical theories at describing nature. Instead of deriving the properties of their systems starting from the many-particle Schrödinger equation (which would be the fundamental equation for an object that consists of a huge number of atoms), they write down simpler models and effective theories that capture more directly the phenomenon to be described. These theories are often even in logical contradiction with the supposed fundamental theory, as explained in the following quote by Nobel laureate Anthony Leggett[1]:

> No significant advance in the theory of matter in bulk has ever come about through derivation from microscopic principles. [...] I would confidently argue further that it is in principle and forever impossible to carry out such a derivation. [...] The so-called derivations of the results of solid state physics from microscopic principles alone are almost all bogus, if 'derivation' is meant to have anything like its usual sense. Consider as elementary a principle as Ohm's law. As far as I know, no-one has ever come even remotely within reach of deriving Ohm's law from microscopic principles without a whole host of auxiliary assumptions ('physical approximations'), which one almost certainly would not have thought of making unless one knew in advance the result one wanted to get, (and some of which may be regarded as essentially begging the question). This situation is fairly typical: once you have reason to believe that a certain kind of model or theory will actually work at the macroscopic or intermediate level, then it is sometimes possible to show that you can 'derive' it from microscopic theory, in the sense that you may be able to find the auxiliary assumptions or approximations you have to make to lead to the result you want. But you can practically never justify these auxiliary assumptions, and the whole process is highly dangerous anyway: very often you find that what you thought you had 'proved' comes unstuck experimentally (for instance, you 'prove' Ohm's law quite generally only to discover that superconductors don't obey it) and when you go back to your proof you discover as often as not that you had implicitly slipped in an assumption that begs the whole question. [...] I claim then that the important advances in macroscopic physics come

> essentially in the construction of models at an intermediate or macroscopic level, and that these are logically (and psychologically) independent of microscopic physics. Examples of the kind of models I have in mind which may be familiar to some readers include the Debye model of a crystalline solid, the idea of a quasiparticle, the Ising or Heisenberg picture of a magnetic material, the two-fluid model of liquid helium, London's approach to superconductivity .... In some cases these models may be plausibly represented as 'based on' microscopic physics, in the sense that they can be described as making assumptions about microscopic entities (e.g. 'the atoms are arranged in a regular lattice'), but in other cases (such as the two-fluid model) they are independent even in this sense. What all have in common is that they can serve as some kind of concrete picture, or metaphor, which can guide our thinking about the subject in question. And they guide it in their own right, and not because they are a sort of crude shorthand for some underlying mathematics derived from 'basic principles.'

The goal of this paper is to show that the claim that nature is at its most fundamental level reversible and deterministic is wrong. First, I want to explain that the time-reversible and deterministic nature of the supposedly fundamental physical equations are in fact idealizations that hold only under very specific conditions. In particular, the studied objects must be carefully isolated from interacting with the rest of the world. By taking a closer look at the areas of physics that are supposedly based on these fundamental equations, I will point out instances where indeterministic and irreversible additional elements are added to the theory when needed. This shows that the programme of deriving everything *only* from the fundamental equations is never realized in practice. I will furthermore argue that indeterminism and irreversibility are closely related, as the first implies the second.

The central part of my paper will focus on the influence of the environment and on top-down effects. By looking at what happens in a quantum measurement, we will see that the environment determines the possible events and their probabilities. This will lead us to a more general discussion of how stochasticity and irreversibility are the result of top-down effects from the context. A consequence of this is a contextually emergent view of nature, where not everything is controlled bottom-up by microphysics but there are also top-down influences from the surrounding context - even from without physics. This prepares the conclusion that while physics underlies everything that happens in nature, it does not determine everything.

2. Irreversibility and indeterminism in the 'fundamental' theories of physics

The following considerations show that no theory that was once or is now thought to be fundamental can do without adding irreversible elements.

2.1. *Classical mechanics*

Classical mechanics is based on Newton's law

$$m\frac{d^2\vec{x}}{dt^2} = \vec{F}(\vec{x})\,. \tag{1}$$

This law is deterministic as the position $\vec{x}$ and velocity $\vec{v} = d\vec{x}/dt$ at a given moment in time determine the future time evolution of $\vec{x}$ and $\vec{v}$. The law is invariant under time reversal as a change of the sign of t does not change the law. Consequently, when a time evolution of $\vec{v}$ and $\vec{x}$ has occurred from time $t = 0$ to $t = t_f$, the reverse time evolution takes place when starting at time t_f and inverting the velocity $\vec{v}$. When applying Newton's law to many particles that interact via mutual forces, the same conclusions are obtained. Due to its impressive success at unifying Kepler's laws of planetary motion and Galileis laws for falling bodies, Newton's theory was considered for a long time an exact and comprehensive description of the physical world, but there have always been cautious voices pointing out its limitations, see.[2,3] Only with the advent of the theory of relativity and quantum mechanics did it become clear to everybody that this view is wrong. Sometimes I wonder why physicists still make this mistake to believe that their most recent theories are exact and universal....

Back to classical mechanics: Even before the mentioned developments in the 20th century, it was clear that classical mechanics cannot do without irreversible elements: When comparing the equations to reality, one needs to include friction. For instance, a pendulum that swings freely under the influence of gravity will eventually come to rest as friction reduces the swinging amplitude with time. When including friction, Newton's law becomes

$$m\frac{d^2\vec{x}}{dt^2} = \vec{F}(\vec{x}) - \eta\frac{d\vec{x}}{dt} \tag{2}$$

with a friction term proportional to the velocity, the strength of which is determined by the friction coefficient η. Even the apparently so perpetual motion of the planets on their orbits is slowed down by friction due to tidal forces.

Classical mechanics also knows stochasticity. As explained so well by Gisin,[4,5] determinism is valid only if position and velocity have infinite precision. But physics is always limited to a finite number of bits when measuring and calculating the motion of objects. For chaotic systems, the time evolution of which depends extremely sensitively on the initial values, this means in practice that prediction of the future time evolution becomes impossible beyond a certain time horizon. There are good reasons to conclude that this indeterminism is not just a matter of our limited abilities, but an inherent feature of nature, see also.[5–7]

If we accept that chaotic systems are inherently stochastic, the irreversible nature of friction is coupled to stochasticity on the atomic level of description: Viewed microscopically, the slowing down of the pendulum is due to collisions of the pendulum with the randomly moving molecules in the air. However, the motion of the atoms is not deterministic since it is chaotic when described by Newton's laws.

2.2. *Classical electrodynamics*

Classical electrodynamics is governed by Maxwell's four equations,

$$\nabla \cdot \vec{E} = 4\pi\varrho \tag{3}$$

$$\nabla \times \vec{E} = -\frac{1}{c}\frac{\partial \vec{B}}{\partial t} \tag{4}$$

$$\nabla \cdot \vec{B} = 0 \tag{5}$$

$$\nabla \times \vec{B} = \frac{4\pi}{c}\vec{j} + \frac{1}{c}\frac{\partial \vec{E}}{\partial t} \tag{6}$$

These equations are again deterministic as an initial configuration of the electric and magnetic fields $\vec{E}$ and $\vec{B}$ and of the charge and current density distributions ϱ and $\vec{j}$ determine the future evolution of the fields, and using Newton's equation for the motion of the charges under the influence of the fields they also determine the time evolution of the charge and current densities.

The equations are also time reversible: When reversing the direction of time and that of currents and magnetic fields, Maxwell's equations remain unchanged. So for each time evolution there is an equally realistic reversed time evolution (as nature knows of no preferred orientation for currents or magnetic fields).

However, there is an important subfield of electrodynamics where the time reversal invariance is broken: This is the emission of radiation from accelerated charges. Using the electrostatic potential ϕ and the magnetic vector potential $\vec{A}$ instead of $\vec{E}$ and $\vec{B}$, the emitted radiation takes the form

$$\phi(\vec{r},t) = \int d^3r' \frac{\varrho\left(\vec{r}\,', t - \frac{|\vec{r}-\vec{r}\,'|}{c}\right)}{|\vec{r}-\vec{r}\,'|}\,, \tag{7}$$

$$\vec{A}(\vec{r},t) = \frac{1}{c}\int d^3r' \frac{\vec{j}\left(\vec{r}\,', t - \frac{|\vec{r}-\vec{r}\,'|}{c}\right)}{|\vec{r}-\vec{r}\,'|}\,. \tag{8}$$

This means that the potentials (and consequently the fields) at a position $\vec{x}$ at time t are determined by the motion of the charges at earlier times $t - \frac{|\vec{r}-\vec{r}\,'|}{c}$, which is simply the time electromagnetic radiation takes to propagate with the velocity of light from the point of origination $\vec{r}\,'$ to the point of measurement $\vec{r}$. All electromagnetic fields thus have localized sources in the temporal past.[8]

When explaining the reasons why emission of radiation is described by the retarded solutions, one has to resort to microscopic stochasticity: Radiation emitted by localized sources is absorbed by walls etc. The reverse process would be that different walls conspire to emit radiation that converges from all directions to a localised sink where it is completely absorbed and turned into motion of electrical charges. However, this 'conspiracy' is argued to be impossible as the atoms of the walls perform random thermal motion and therefore emit incoherent thermal radiation and not radiation that is correlated over large spatial scales. The thermal motion of the wall atoms is considered to be stochastic.

There is a second way how stochasticity enters electrodynamics: When trying to describe what happens at the atomic scale when light is emitted, one needs to resort to a quantum version of electrodynamics, which is quantum electrodynamics and describes the emission of light in terms of the stochastic emission of energy quanta (each containing an energy $\hbar\omega$ with ω being the frequency) from the source. And this brings us to the next section, which deals with quantum mechanics.

2.3. *Quantum mechanics*

The basic equation of nonrelativistic quantum mechanics for one particle is the Schrödinger equation

$$i\hbar\frac{\partial}{\partial t}\Psi(\vec{x},t) = \hat{H}\Psi(\vec{x}) \tag{9}$$

with the Hamilton operator

$$\hat{H} = \frac{\hat{p}^2}{2m} + V(\vec{x})\,. \tag{10}$$

Here, the first term is the kinetic energy, and the second the external potential. Given the initial state $\psi(\vec{x},0)$, the state at other times t are given by the relation

$$\Psi(\vec{x},t) = e^{-i\hat{H}t/\hbar}\,\Psi(\vec{x},0) \tag{11}$$

if the potential $V(\vec{x})$ is not explicitly time dependent.

This equation is deterministic. This means that the initial state, combined with the Hamiltonian determines the future time evolution. It is also invariant under time reversal: The time-reversed Schrödinger equation is solved by the complex conjugate wave function Ψ^*, and this does not affect the observables as they are calculated from expressions that contain products of Ψ and Ψ^*. All this holds also for the many-perticle version of the Schrödinger equation.

However, quantum mechanics is incomplete without a rule for how to calculate the outcome of a measurement. And this rule says that out of all possible measurement outcomes of an observable, one of them (let us call the corresponding state ϕ_n) is chosen stochastically with a probability that is given by $|\langle\phi_n|\Psi\rangle|^2$. This process is irreversible, as the reverse process (that the measurement apparatus or photographic plate returns to the pre-measurement state and emits the particle that has been absorbed during measurement) is not observed in nature. In this way, quantum mechanics includes from the onset irreversibility and stochasticity. There are a number of interpretations of quantum mechanics that attempt to explain away this dichotomy between the Schrödinger equation and the measurement process by describing also all the atoms of the measurment device by quantum mechanics, usually invoking decoherence in one way or another[9]; however, to many people these interpretations remain unsatisfactory as they cannot really explain why in a single run of an experiment only one of the possible outcomes is observed.[10,11] In one way

or another, stochasticity kreeps into any interpretation. It does so even in Bohmian mechanics, where all stochasticity of the future time evolution is contained in the random features of the initial state.

2.4. *Quantum field theory*

The theory that is often considered the most fundamental one is quantum field theory, which is a relativistic theory for many particles and has several building blocks that take into account the different types of interactions and particles. It is a combination of the Glashow-Salam-Weinberg model for the electroweak interaction and of quantum chromodynamics for the strong interaction. Just as for nonrelativistic quantum mechanics, this theory includes two parts. Unitary time evolution according to a Hamilton operator is only applied between preparation and measurement of particles. The measurement outcome (e.g. of a scattering experiment or particle collision experiment) is again described by a probability that is calculated in a similar way as above. This means that everything written above for nonrelativistic quantum mechanics applies also to quantum field theory.

2.5. *Thermodynamics*

Thermodynamics is considered fundamental only by some scientists. But these scientists argue that thermodynamics might be even more fundamental than the other fields of physics. The most famous quotation in this direction is by Sir Arthur Eddington (From his book *The Nature of the Physical World*[12]):

> The law that entropy always increases holds, I think, the supreme position among the laws of Nature. If someone points out to you that your pet theory of the universe is in disagreement with Maxwell's equations - then so much the worse for Maxwell's equations. If it is found to be contradicted by observation - well, these experimentalists do bungle things sometimes. But if your theory is found to be against the Second Law of Thermodynamics I can give you no hope; there is nothing for it but to collapse in deepest humiliation.

Einstein had a similary high opinion of thermodynamics:

> A law is more impressive the greater the simplicity of its premises, the more different are the kinds of things it relates, and the more extended its range of applicability. [...] It is the only physical theory of universal content, which I am convinced, that within the framework of applicability of its basic concepts will never be overthrown.

Now, the second law of thermodynamics is about the irreversibility of nature: All processes run in the direction in which the entropy of the universe increases. The relations of thermodynamics can be obtained also from a microscopic description,

which is that of statistical physics. But statistical physics is not deterministic, as it is based on probabilities for the different possible microscopic states a system can take. This means that we have again a link between irreversibility and stochasticity in this field of physics.

3. A reversible, deterministic theory cannot give irreversibility

It is often argued that a 'fundamental' microscropic theory that is deterministic and reversible, such as classical mechanics or quantum mechanics, can give rise to irreversibility. Even textbooks on statistical mechanics often make this claim and use arguments based on coarse-graining. In this section, I will demonstrate that the 'derivations' of irreversibility from a microscopic reversible and deterministic theory all employ additional assumptions that are not part of the theory. They all invoque stochasticity or randomness in one way or another and are therefore not truly deterministic. As soon as stochasticity is employed, irreversibility follows naturally. The first subsection will argue that stochasticity leads to irreversibilty, and the second subsection will show how stochasticity is smuggled into the derivations of the second laws of thermodynamics from classical mechanics.

3.1. *Stochasticity gives irreversibility*

In the previous section, we have seen that irreversible processes are always coupled to stochasticity when considered on the atomic level, for instance when friction is described in terms of atomic collisions or when the approach to thermodynamic equilibrium is described by stochastic transitions between different microscopic states. More general considerations suggest that irreversibility and stochasticity are indeed intimately connected: Progress of time is perceived via changes. These changes occur in the form of events. Whenever one of a set of possible events occurs, the open future becomes the definite past. Thus, events are both irreversible and stochastic. There are several theories that are based on such events constituting the fabric of spacetime itself on the Planck scale.[13,14] But we need not know the most fundamental level in order to see that any stochastic event is also irreversible. This is because once the event has occurred the state prior to this event cannot be retrodicted. For a quantum measurement, e.g., the outcome does not allow to reconstruct the incoming wave function. A stochastic event itself is a step by which an indeterminate future gives way to a definite outcome. Against this, it is sometimes argued that probabilities can also be applied backwards for retrodiction. Yes, but this is qualitatively different: probabilities used in retrodiction are either Bayesian probabilities that are based on incomplete knowledge of the past, or they are frequencies in an ensemble of events. In principle, the past that precedes a given event is fixed in either case. In contrast, the future is not fixed if stochasticity is real and not merely apparent.

3.2. *The hidden assumption in so-called 'derivations' of the Second Law from classical mechanics*

In the following, I will use classical mechanics to demonstrate that additional assumptions are smuggled in when irreversibility is 'derived' from a reversible deterministic theory. A similar type of argument can be made for the supposed derivations of the Second law from a many-particle Schrodinger equation.[6] In both cases, the additional arguments are randomness of initial conditions and of statistical independence of degrees of freedom. The main ideas behind the 'derivations' of the Second Law from classical mechanics are as follows:

(i) A gas is modelled as a conservative mechanical system of $N \simeq 10^{23}$ small balls with hard-core repulsion, enclosed in a container of volume V with perfectly reflecting walls. Since energy does not change during time evolution, the trajectory of this mechanical system in $6N$-dimensional phase space stays within the $6N-1$-dimensional energy shell in which the initial state is placed. (ii) It is generally assumed, even though this is not proven, that the dynamics of this system is ergodic. This means that a "typical" trajectory approches each point of the energy shell with arbitrary precision ϵ if enough time has passed. Or, equivalently, an initially small and compact phase-space volume of dimension $6N$ (representing an ensemble of very similar initial conditions) will become stretched and folded to the extent that eventually some part of it will be in every small volume of size ϵ^{6N-1} in the energy shell. (iii) The vast majority of cells of size ϵ^{6N-1} correspond to macrostates with maximum entropy, which have (among other properties) an even distribution of density over the entire volume. (iv) Therefore, if starting in one of the few cells that correspond to a low-entropy initial state, after sufficiently long time the state of the system will 'almost certainly' be in a cell of maximum entropy.

Of course, each of these steps could be discussed in depth, in particular the starting assumption of infinite-precision phase space points and infinite-precision trajectories. I will focus on the last step and accept all preceding ones for the sake of brevity. In this last step, additional assumptions creep in: The last step is based on the assumption that the trajectory taken by the system is a 'typical' trajectory, or, equivalently, that among all the possible initial states that lie within the initial energy-shell volume element, the true initial state is a randomly chosen one. This is an assumption of randomness of the initial state. The laws of classical mechanics would not be violated if all particles of the gas would gather in irregular time intervals in some corner of the container. Among all possible initial states that agree with each other within a desired degree of precision, there would be particular initial states that show such an atypical behavior. We therefore have to introduce the additional assumption that the 'true' initial state is not such an 'atypical' one that leads to unexpected low-entropy future states. This is somewhoat similar to what one does in electrodynamics when ruling out spatially localized sources of radiation that lie in the future.

Instead of postulating random initial conditions, one could equivalently argue that the initial state is not fixed with infinite precision but only with finite precision, and that randomness comes in as the time evolution of the system proceeds and more and more bits that were not fixed initially become relevant for fixing the ongoing time evolution. In my view there are many reasons to prefer this latter perspective, and it has been defended most forcefully by Nicolas Gisin.[5]

But there is more to stochasticity than that it is always added to 'deterministic' theories when real-world problems are addressed. Stochasticity depends on context. The next section focuses on this issue.

4. Stochasticity is context dependent

We have seen above that whenever the environment of a system is included irreversibility comes in: In mechanical systems, the environment causes friction. In electrodynamics, considering the emission of radiation means that there is an environment into which this radation can be emitted. In quantum mechanics, the interaction of a quantum particle with the rest of the world, which is here represented by a measurment device, causes the irreversible measurement event. Thermodynamics is a very interesting field of science from this point of view as it is a prime example of the environment determining what happens in a system: The environment imposes the temperature and the chemical potential. The environment performs changes on the system (such as pushing a piston or connecting a hot and a cold object) the effect of which is calculated in thermodynamics problems.

It is usually not acknowledged that stochasticity also requires a context. Karl Popper emphasized it in his paper "The propensity interpretation of probability",[15] where he argues that probabilities are defined only when the conditions under which the experiment is to be repeated are specified. Probabilities are thus defined relative to a setup in which the event of interest occurs. Popper justifies the propensity view by the findings of quantum mechanics. Indeed, the "fundamental" stochastic event is a quantum event. Its standard example is a measurement. Let us take for illustrative purposes the Stern-Gerlach experiment. It is the simplest quantum measurement as the observable to be measured is a spin-1/2, with only two measurement results, which we denote as $|+\rangle$ and $|-\rangle$. The measurement device measures the spin with respect to direction chosen by the experimenter. Let this direction be the positive z direction. If the incoming particles have not been polarized such that they point in the z direction, both measurement outcomes $|+\rangle$ and $|-\rangle$ are possible, and their probabilities depend on the preparation procedure. Now, the experimenter could have chosen to measure the spin with respect to another direction, for instance the x direction. In this case the possible measurement results would be again $|+\rangle$ and $|-\rangle$, but now these two results signify an orientation parallel or antiparallel to the direction of the x axis and no longer to the z axis. In general, the probabilities for the two measurement results are also different compared to a measurement in z direction.

This example demonstrates that the possible events and their probabilities are not an intrinsic property of the quantum particle but the combined effect of the way how the quantum particle has been prepared and of the measurement device. Had the experimenter chosen to measure position or energy instead of spin, the possible results and their probabilities would again have been different. Had the experimenter decided not to perform any measurement, the quantum particle would have remained in the state generated by the preparation procedure.

Now, quantum measurements are just one class of quantum mechanical events by which a quantum particle undergoes an irreversible, stochastic transition and exchanges energy with a macroscopic, finite-temperature object (which is a classical object). There need not be an experimenter, the particle could interact with the rest of the world in a different way. Examples are nuclear fusion reactions in the core of the sun or the emission of photons into space from the warm surface of the earth. Again, the fact that these events happen and their probabilities depend on the context.

So far, not many models for quantum measurement take this context explicity into account. Many authors, however, speak in a more general sense of quantum contextuality.[16,17] The Copenhagen interpretation of the measuremeent process makes an explicit distinction between classical objects (the measurment setup) and quantum objects, but does not detail how this difference arises. More explicit considerations of how the context is involved in a quantum measurement are advanced by Ellis[18] and more recently by Drossel and Ellis.[11]

This insight that there is a top-down effect from the environment or the larger spatial scale to the quantum particle leads us to the next section where we introduce the concepts of contextual emergence and top-down causation.

5. Contextual emergence and top-down causation

Physics is viewed by many people as a reductionistic science where the properties of an object are derived from its parts and their interactions. Consequently, those theories that deal with the most microscopic objects (i.e., particle physics and quantum field theory) are considered to be the most fundamental ones and to describe, at least in principle, everything that occurs on larger scales. But this is a one-sided view that ignores the various ways in which the context or the larger structure influences what happens at a smaller scale. To understand this better, it is useful to think of nature as a hierarchy of objects, with the objects on the lower level being the parts of the objects on the next hierarchical level. For instance, one can build the hierarchy Elementary particle - Atom - Crystal - Earth - Solar system - Galaxy - Universe; or, choosing a hierarchy that involves us humans: Elementary particle - Atom - Molecule - Cell - Organ - Individual - Society.

Now, describing an object in terms of its parts and their interaction is practised successfully by all scientists. For instance, describing the conducting properties of a metal, physicists build a model of electrons performing collisions with the lattice

defects and the lattice vibrations (the so-called phonons) of the metal. Or, when exploring the cycle of growth and division of a biological cell, scientists describe this process by a network of molecular interactions and reactions. This success of the reductionist procedure often veils the view for the top-down influences that are equally important: The metal block provides the environment for lattice vibrations to exist, and the temperature of the metal block determines how many phonons of which frequency are present. The lattice structure of the metal determines what the conduction bands of the metal look like and thus strongly affects the way how electrons can propagate in the material. The wider context, such as the connection to a power supply is the prerequisite for conduction happening at all. Similarly, the growth and division of cells is regulated by mechanical and chemical cues from the embedding tissue to which the cell belongs. Furthermore, the cell depends on a continuous supply of nutrients and building material from its environment. For any other system of the hierarchies mentioned above, we can similarly list a variety of top-down influences of the whole on its parts. This topic of top-down causation is discussed extensively by George Ellis in his book "How can physics underlie the mind".[19]

All this means that reduction, successful as it is, is only part of the story. The complement of reduction is emergence: while reduction considers how the whole can be explained in terms of its parts, the concept of emergence considers the qualitatively new properties of the whole, which are not properties of the parts. One distinguishes between different concepts of emergence. Proponents of weak emergence hold that the emergent properties, even though they appear surprising and qualitatively different from the properties of the parts, can ultimately be fully accounted for by the properties of the parts. For a physicist this means that the theory describing the parts and their interactions contains at least implicitly all the phenomena observed in the whole. It is closely associated with a reductionist view. In contrast, proponents of strong emergence hold that the emergent properties are explained only partially by the parts and their interactions and cannot be fully reduced to them. The notion that captures best the type of strong emergence that occurs in physics is that of contextual emergence. It emphasizes that the existence of the parts and their properties depend on the context, the boundary conditions, etc. Until know, strong (or contextual) emergentists are a minority among physicists. The reductionist paradigm prevails despite the many good reasons to question it.

With this understanding of contextual emergence and top-down causation, we will gain a deeper understanding of how indeterminism enables our experience of the passage of time and of being agents.

6. Indeterminism and top-down causation

It is often argued that indeterminism is of no help at justifying free will and agency. The reason given is that stochasticity is completely random in the sense that random events are not influenced by anything else and can therefore not be part of

a conscious act or decision - which is not random but follows logical reasoning or is based on values. However, our discussion of the quantum measurement process above has shown that stochastic events are not completely random. On the contrary, the possibility of these events and the nature of these events is set by the context. This is not appreciated very often. Karl Popper made the interesting suggestion that chance at the lower level is necessary for top-down causation from the higher level,[20] and he has been criticized for it.[21] But I think that he is right, and so do others.[7] Only when the entities at the lower level are not fully controlled by the microscopic laws can they respond to the higher level.

In biological systems, the influence of the environment on the types of stochastic events and their effects is evident at all levels: Let us take gene expression. The process by which transcription factors bind to the promoter region of a gene and enable transcription has many random elements, as diffusion and binding of transcription factors is subject to thermal noise. However, the context determines which transcription factors are activated at all. For instance, when I experience joy, this triggers the discharge of endorphins, which in turn stimulates the production of further endorphines via gene expression. On a larger timescale, evolution has shaped the transcription factors that we possess and the affinities to the different genes, resulting in the binding and dissociation rates that characterize the stochastic dynamics in our cells.

As another example, consider the brain. The neurons in our brain fire "randomly". At the same time, this electric activity reflects the brain activity, for instance while I formulate the text of this paper and type it. There is a wider context that influences the stochastic events in the brain: The past experiences have shaped the connection patterns and the strengths of the synapses of our neural network, and this in turn affects how activity propagates through the network and which neurons or groups of neurons are triggered by which others. Although there is randomness in the individual firing events of neurons, and on a more microscopic level in the opening and closing of ion channels, the frequency of firing and the neurons involved and the temporal sequence of which regions become active and which output neurons pass the signal on (for instance to my fingers while I am typing) is not random at all. Somehow it even reflects my creative activity while I develop my arguments for this text.

The constructive role of randomness in biological systems is discussed in more depth in several review articles.[22–24]

7. Conclusions

The view of physics that I have defended in this article is very different from the reductionist view that is propagated in many textbooks. The main problem with that view is that theories are applied far beyond their range of applicability. Any physical theory is an approximation and not an exact description of the physical processes of interest. And by no means it is a complete description of everything that

is going on in the physical world. I have argued that even though the supposedly fundamental theories are deterministic and time-reversible, these theories are in practice supplemented by irreversible and stochastic features. There is no reason to assume that irreversibility and stochasticity are only apparent. Such a claim is based on ideology and not on evidence. I have argued that irreversibility and stochasticity enter when the influence of the environment on a system is taken into account. This focused the attention on the often-neglected topics of emergence and top-down causation. It is the context that sets the stage for the possible events that can happen in the system, and the context also influences the probabilities of these events.

It follows that our experience of time flowing and us being agents that can influence what happens is not contradicted by physics. Physics enables everything and underlies everything, but it does not determine everything. On the contrary, physics appears to be sufficiently complex to allow even life and consciousness to function on a material platform.[19] This bears some resemblence to Turing machines in computational science, which are complex enough to allow for any possible type of calculation.

Top-down influences come in different shapes. Top-down causation from the wider material context is easier to understand but is only part of the story. In particular the two biological examples of Section 6 illustrate that there is also an influence from the nonmaterial world of ideas, rationality, goals and desires on the activity of our genes and neurons. It may well be that physics will never find an access to describing these influences. The goal of my paper is far more modest, namely to make the case that physics cannot rule out that these influences are present. Physics is not causally closed and does not encompass everything that happens in our world.

To conclude, we should not let naive interpretations of the laws of physics constrain our view of reality. On the contrary, we should trust our most immediate experiences that are the basis for us being capable of thinking and acting, and based on these we should critically examine those simplistic metaphysical claims.

Explaining time's passage

Jonathan J. Dickau

The way we experience time is in the accumulation of experiences and events that happen in the moment, and then are behind us. Since the time of Anaximander at least; philosophers have tried to explain both the nature of time and its origin or basis. In modern times; scientists are the ones exploring the domain of time, so now *they* attempt to explain the nature and basis of time – with varying degrees of success. This is complicated because explanations from Classical Physics or Relativity are different from, and incompatible with, answers from Quantum Mechanics, so we hope Quantum Gravity theories will help resolve this. Recent advances in Mathematics hold promise for a unified basis explaining both the thermodynamic and quantum-mechanical time arrows in a way that consistently informs our Philosophy. However; we may need to explore beyond the island of familiar Maths, to reconcile the divergent pictures of how and why time passes.

Keywords: Origin of time; passage of time; basis of time; Philosophy of time; Physics of time.

1. Introduction

While we imagine time is a single entity; the reality of time is more complex and more interesting. As far back as Anaximander[1]; philosophers have tried to make sense of that complexity, and his analogy of stepping into a moving stream actually comes very close to the reality we observe, since things keep moving while events are happening. So the simplest realities of life are governed by a rule that assures most decisions will be complex instead of simple. Coupling Plato's observation "time is the image of eternity[2]" with the insight that space is a projection of infinity can help us make sense of his deeper message. But then; we see glimpses into quantum gravity from the ancient Greek philosophers. Rovelli's book "Reality is Not What it Seems[3]" wonderfully recounts insights from those individuals that extend to topics including quantum gravity and the nature of time. While I agree with his view that we find the seeds of quantum gravity and the birth of atomism among ancient philosophers; we differ somewhat on whether time is fundamental or primordial on that basis. The resolution involves both cosmology and quantum gravity. So this paper explores how recent developments in Mathematics might have a deeper relevance than was previously appreciated to advance our understanding of time. I will discuss the examples cited above in greater detail and offer unique insights from my own research.[4,5]

Already in 1922, concluding a debate with Bergson; Einstein said "There is no such thing as the time of the philosopher.[6]" So for some it is a dead issue. But the debate goes on in the Physics community and among modern philosophers, over the consequences of how physical theory affects our understanding of time. This debate centers on the sharply differing views of time in Relativity and Quantum Mechanics. And there is strong evidence both views must be true. So if the traditional outlook is that time is a single entity for all; that view is broken. But this emphasizes the need to create new ways to conceptualize what we have learned in Physics and incorporate it into our Philosophy.[7] And yet; Anaximander's ancient view of time as a stream which continues to flow even as you are stepping in it remains enlightening in modern times. So there is hope for reconciling Physics with Philosophy, and knowledge that by developing quantum gravity theories; we gain a better philosophical understanding of time. I think the reverse is also true; it is easier to choose or develop better approaches to quantum gravity, by understanding the Philosophy of time better. Prevailing QG theories share many features and predictions with considerable common ground to explore.[8] So I examine ideas of Connes,[9] Longo,[10] Gisin,[11] as well as Drossel and Ellis,[12] on the emergence of time from quantum gravity, with some unique insights on wavefunction collapse from Dieter Zeh,[13] and a discussion of the possibility of global asymmetry as it applies to whether time is primordial or fundamental.[14]

2. What Is There to Explain?

If we had a better understanding of the extreme micro- and macro-scale in Physics; time would not be an enigma at all. But from my view; people are unaware they live in the 'Goldilocks zone' on an island of comfortable norms. The realm of familiar Maths is perfectly sufficient for exploring anything anywhere on the island; so who could want more? Theoretical Physics seeks the origins of events of our current surface-layer reality in deeper layers or causal elements further back in time. But if we cut ourselves off from the possibility those origins are higher-dimensional; we omit some probable realities that solve standing problems in Physics. This is because evolutive properties arise unavoidably when the underlying or governing algebra is non-commutative or non-associative. Time's passage may thus be caught up in how higher-order spaces are reduced in dimension through cosmological transitions to obtain a cosmos with familiar properties, such as the one we inhabit. Evolution arises automatically if the dimensions are high enough, as any system's degrees of freedom approach infinity; so it becomes almost certain that a space or its underlying algebra will evolve, or is self-evolving, once certain initial conditions are met. This involves a unit of minimum uncertainty or action, and at least a modicum of energy; but physicists observe that these conditions are handily met at the Planck scale. One might question creating something from nothing, but we are uncertain absolute nothing ever existed. So there is little argument, about reasons for time to move

inexorably forward, if we assume the universe started from variations or variability and moved toward conditions.

And yet; people ask "what can cause numbers to change on their own or physical parameters change of their own accord?" It seems more reasonable to accept that virtual particles can pop in and out of existence in pairs, rather than that objects and spaces are evolving processes. But to explain time; we may need to accept that everything evolves on its own, unless it is otherwise constrained. To understand why time passes; I suggest we start with the assumption that objects and spaces are not necessarily static or fixed, and could be inherently time-evolving. This is precisely what Alain Connes proposed, when in 2000 he emphatically wrote "Noncommutative measure spaces evolve with time![15]" This result is based largely on the findings of Tomita[16] and Takesaki[17] studying modular Hilbert algebras, but Connes has generalized that work to create a new kind of differential geometry. This methodology is more nearly universal than people are aware of, however. Even if some of his ideas are not verified by current evidence; his line of reasoning is not falsified thereby, because intrinsic time evolution undeniably arises in higher-d Maths. This idea or the broader context it suggests provides a framework for a more realistic yet more flexible view of time. In this view time is, at its root, inherently or automatically progressing; originating from the dynamism of intrinsic evolution of forms and spaces in higher dimensions because the non-commutativity and/or non-associativity of their underlying algebra induces algebraic and geometric directionality and/or sequentiality.

This approach offers a unified basis for the quantum-mechanical and thermodynamic arrows of time that resolves some paradoxes or quandaries. If we see time in the tendency for objects and spaces to evolve automatically, once the degrees of freedom are high enough; we have a way to unite the Math and the Physics of time that resolves the paradox of differing time arrows from various models. This is perhaps a more major advancement than has been appreciated to this point. It restores seeing time as an accumulation of experiences or events that occur and are then behind us in a view of Quantum Mechanics where Heisenberg's uncertainty or 'unsharp measure' is due to spacetime being non-commuting. All interactions or observations accumulate because quantum-mechanical reality is like Anaximander's stream. But if we assume the evolution of the early cosmos was higher-dimensional too; we can extend intrinsic time to canonical time evolution in the initial origin at the Planck time through the inflationary period at least until baryogenesis, and likely continuing to play a part until decoupling or recombination occurred, or at a 5-d $\rightarrow$ 4-d boundary[18,19] that is seen as a black hole $\rightarrow$ white hole transition[20,21] in some theories. Time evolves from higher-d spaces through cosmological transitions, in these models. The Aikyon theory of Singh[22,23] employs Connes' intrinsic time and the octonions to explain both cosmic origins and particle physics without such transitions, but affirms other aspects of my present work. So we now examine a proposed basis for these varied ideas.

3. Explaining What We Observe

Great successes in Physics assume what we observe is built and can be explained from the bottom up, from the smallest components or the simplest applicable formulas, but there is another way to explain what we see, where nature employs top-down methods taking advantage of higher-order and higher-dimensional mathematical forms, as well. If we allow a broader spectrum of possibilities at the cosmos' origin, by assuming that both bottom-up and top-down strategies are at work at the same time; a picture emerges where dimensionality has an upper and lower limit at the outset of geometrogenesis, which later converges toward a single value.[24] This lets emergent forms be shaped by higher-d figures like the Monster Group and E_8, during the earliest phases of cosmological evolution, even while they are being built from lower-d components. From this radically top-down outlook, even when coupled with causal structure theories of quantum gravity; the conventional view using bottom-up reasoning is inside-out, and we need a view where we see the universe from the outside-in, to fully understand it. The disparity is partly due to the way most people have learned Maths, where the simplest elements are taught first and advanced ideas are derived from the simplicities. However; we know there are patterns that emerge in complex structures from which simple rules can be derived.

This dichotomy is called additive vs. formant synthesis. In the one case; you add bits of clay to make a sculpture or individual harmonic tones to create the desired waveform, while in the other you chip bits away from the outside or remove some overtones from a more complex waveform, to obtain the desired shape. Here I propose that nature has utilized and always uses both methods to shape the cosmos. It builds larger and more complex forms using smaller pieces, but it also pares physical reality down from a palette of possible forms, and borrows structure from more complex forms to create simpler ones. In this way; nature can employ the full range of Mathematics and exploit the true organizing power of what resides in higher dimensions. But the outside-in view is difficult to obtain on the island of common Maths where mathematical structures are built from the bottom-up, rather than inherited from orderly patterns in higher-level structure. To gain *that* view we need to look beyond the familiar island where features like commutativity and associativity can be taken for granted, and explore the unfamiliar expanse of non-commutative and non-associative algebras and geometry. Luckily mathematicians have already charted a lot of the content that exists in higher-d spaces, and we are learning how some of it works to shape the laws of Physics. A clear example is found in the normed division algebras, and in the reduction of the octonions to the quaternions, the complex numbers, and the reals.

$$\mathbb{O} \supset \mathbb{H} \supset \mathbb{C} \supset \mathbb{R} \tag{1}$$

The octonions are the most general number type, 8-dimensional with one real and seven imaginary parts but are non-associative; the quaternions are 4-d with three imaginary parts but are non-commutative; the complex numbers have one real

and one imaginary part, but are well-behaved; and only the reals encode a constant value. Imaginary numbers encode variation or the freedom to vary by a specified amount in a certain direction or orientation. Though they are the granddaddy of familiar types, the octonions are thought to be weird and difficult.[25] Viewing the imaginary dimensions as rotations; the octonions reduce to the quaternions if 4 of their 7 axes are fixed, that reduce to the complex numbers if 2 of the remaining 3 are fixed, and if the last rotation is halted, only the real-numbered value remains. The octonion algebra itself is a reduction because 480 possible multiplication tables before choosing a starting place and direction reduce to 16, 8 left- and 8 right-handed algebras.[26] And once any table is chosen, we must employ only that one table thereafter. Each step in any octonion calculation thus proceeds from optiony toward specificity.

$$Smooth \supseteq Top \supseteq Meas \tag{2}$$

$$Gas \supseteq Liquid \supseteq Solid \tag{3}$$

In the relations above; we see this pattern of moving from variability or variations to definite conditions as a more general bridge between the fields of Math and Physics that needs to be further explored. Moving from left to right; we see that acquiring a surface or boundary makes a space or object topological, or indicates a phase change from a gas to a liquid state. Then having a fixed metric makes objects or spaces measurable, or indicates the transition or phase change to the solid state. This reflects the sensibility of the earlier expression where applying successive constraints to the octonions eventually gets us to the real numbers. We observe that evolutive properties arising from directionality in higher-d Maths project onto or influence what comes after, such that things tend to evolve from highly variable states toward specific conditions and discrete possibilities. One might question the applicability of this line of reasoning to real-world Physics or everyday life. It certainly has a place for answering questions in early universe Cosmology, in Quantum Gravity, and the underpinnings of Quantum Mechanics. But the actual footprint of non-commutative and non-associative algebra and geometry is scarcely known. That is why it is important for today's Physics researchers to look into evolutive properties that arise in these Maths, as a possible source or root cause for the evolution of time.

The idea that spaces with certain properties have a built-in time evolution is neither well-known nor well-understood, except among a handful of ardent researchers in this arena. But when Tomita[27] opened that door, by discovering intrinsic evolution in modular Hilbert algebras; Connes and others were quick to apply that notion to a broader class of objects and spaces. To walk through that door, we must go beyond the island of familiar Maths and embrace the idea that non-commutativity and non-associativity are more of a blessing than a curse to Physics,[28] because they assure directed evolution. But we must first accept that if reality is quantum-mechanical, non-commutative ordering factors automatically arise

due to Heisenberg uncertainty making the space we live in non-commutative. Notably; this issue also arises in Relativity[29] as factor-ordering problems sometimes, when applying the equivalence principle. However, it happens often. Cycles of action must be undertaken in a specific sequence both when doing octonion algebra and with common tasks like painting or baking,[30] where a process of ratcheting accumulation happens in both cases. So the demands of additional rules of order and sequence one must learn to use non-commutative and non-associative algebras are not unnatural or onerous, and in fact represent the same laws of directional evolution all natural processes must follow.

$$\delta: \rightarrow \mathrm{Aut}(M) \tag{4}$$

Connes[31] uses the above expression, where $\mathrm{Out}(M) = \mathrm{Aut}(M)/\mathrm{Int}(M)$ the quotient group of automorphisms of M by its normal subgroup of inner automorphisms, to show how modular or Tomita flow gives rise to intrinsic time evolution. He emphatically asserts that non-commutative spaces evolve with time and this is greatly expanded in recent work by Longo,[32] showing why non-commutative spaces must evolve, and explaining the basis for time's emergence in detail. Non-commutativity is enough to assure time will evolve, and we undeniably live in a space that is non-commutative. The background state of physical reality is not what Classical Physics would imagine a vacuum to be, a static space absent of contents. We can point to quantum uncertainty or virtual particles to explain this, but time's directionality can also be seen to result from residing in a higher-d spacetime instead of 3-d space plus time. Longo extends Connes' arguments to a more robust connection between quantum mechanics and thermodynamics using the language of operator algebras, and shows how time emerges as a result. But he sees this as resulting from wavefunction collapse, and I do not see emergent time as dependent upon that feature. Here I remind the reader of an outside-in view offered by Dieter Zeh[33] suggesting that the global wavefunction is more real or fundamental than particles or quantum transitions, and persists while we measure. But recent work by Peter Morgan,[34] using the Koopman-von Neumann formalism, suggests we can choose between collapse and no-collapse models depending on the context, so long as we talk about subsequent measurements rather than states.

Things go from possibility toward actuality. However; this dynamism does not depend on properties arising in higher-d spaces and hyper-complex algebras or from infinities, as in the above examples, so higher-d attributes are not essential for top-down mechanisms to work. Gisin[35] points out that even real numbers, which are commonly viewed as fixed quantities, are only fixed by a process of determination. From an intuitionist view; the exact or precise value of a quantity is not known before it is determined in a process. So if there is a specific real number with a large number of digits; we may not find out what extended values are for a long time, and information on what is beyond a given point is no better than random data. This is like a stochastic background in the realm of the indeterminate, which influences our view of time. Gisin speaks to this issue[36] and also has novel ideas

about wavefunction collapse.[37] This work informs the Contextual Collapse model of Drossel and Ellis,[38] a top-down approach which treats the quantum measurement problem in detail, where measurement is by nature a multi-stage process. Their work addresses shortcomings in decoherence theory and other models, which they handle individually, concluding that a robust description includes both Quantum and Classical elements because any physical measurement unavoidably includes a mix of both, depending on the context. They further extend the conversation to how quantum measurements are a special case, projections of the wavefunction; of a larger class they call events which are ubiquitous in nature.

4. What Kind of Philosophy Is Best for Physics?

Is there a single best Philosophy of Physics? While some would argue that learning Philosophy is a side trip for those learning Physics; that in itself is a Philosophy about how Science is done. So it is unavoidable that the two are interwoven. This is aptly illustrated by Rovelli[39] in his paper arguing that Philosophy and Physics need each other, contrasting the schools of Isocrates and Plato. While Isocrates taught that practical skills and their application should be cultivated; Plato advocated the quest for knowledge of how or why things work, and how they came to be as they are. While Plato was among the first to be called a philosopher; we put both in that category in modern times, and their teachings are seen as two competing schools of Philosophy. Aristotle argued that general theory supports practice, and one can argue that both approaches are needed to make progress in some areas. But the debate about which philosophy is best goes on today, writ large on the face of politics. This influences funding for all areas of Science, depending on the philosophy of the prevailing political party. This split is seen to be connected to our perception of time, in that liberals have a more forward-facing view, being focused on creating a better future, while conservatives tend to focus on preserving the legacy and traditions of our past, which is more rearward-facing. Here again; people fiercely debate which philosophy is correct, or benefits us most, rather than seeing that both viewpoints are needed.

If asked what kind of Philosophy is best for Physics; I would advise people to seek an inclusive or encompassing view of reality. We need to be explorers, unafraid to look beyond the boundaries, if we want to make important discoveries or developments. And we must be wary of information silos that present a self-consistent but wrong-headed view of the world. The incorrect usage of the word recombination persists in astrophysics, for example, to describe what happens at the horizon of last scattering during decoupling; even though early-universe cosmology tells us nuclei and electrons never were combined into atoms before then. This illustrates how skilled scholars work on an island of familiar and comfortable norms, with fierce pressure to remain within the bounds of their area of specialization. The self-consistent view within the silo is often reinforced by walls that are polished

mirror smooth. An outsider and generalist like myself gets a different view from others when attending quantum gravity lectures, for example, because the common ground stands out as starkly as the differences between approaches, and I have no need for a clear winner. I think all of the current lines of research inform us in useful ways, and are not mutually-exclusive. But we should not stop exploring or seeking other options to explore, just because we have some viable explanations for gravity on the table.

So the ideal Philosophy for Physics always leaves the door open to learning more about what we think we know, discovering something new or unexpected, and so on. We are unavoidably inside a construction that is the cosmos, and further limited because we can see only what is within the Hubble radius. We are on the inside, looking out at the larger cosmos. This is why I advocate seeking the outside-in view of Math and Physics, as a radical extension of the top-down view, and as a possible cure for the view that making things from the bottom-up cannot only create all form but aptly explains all we see. A basic fact about explorers is needing somewhere to explore. Perhaps we need to get off-planet to obtain the perspective we need for the outside-in view beyond our limitations. Or maybe we only need to seek that perspective from higher ground philosophically. To see a circle in its entirety; one must be off the page, in the 3rd dimension. Likewise; to draw that circle, one must be in a dimension one higher than the surface on which you are drawing. If this as a general pattern; there is always a need to discern what the structure we are living in would look like from one dimension higher. But the block universe of General Relativity, of spacetime as seen from the outside, is a severe limitation. So we need to frame other constructs that give us better scaffolding for our ideas of the view from out there. And that is the main thrust of this paper; to inspire others who might help to create that structure.

When entertaining questions about Philosophy and Physics; one cannot forget the way Mathematics always makes its way onto the scene. Plato brought to light the notion of a mathematical ideal or archetype which is projected onto physical reality. We now have a much more sophisticated notion of how that works, but the idea persists to this day. I think we need to be hyper-dimensional Platonists, with a guide to the Atlas of Lie Groups[40] in every College library where they teach higher-level Math and Physics subjects. In this way; we will speed up the process of discovery fueled by what we know. But we need to introduce some ideas at an earlier age, so tomorrow's young people will have the benefit of what we as adults already know. This is what David Blair[41] seeks to do with the "Einstein First" program, which teaches advanced concepts based on our latest knowledge, and then works that back into the structure of what students have already learned. This allows young people to benefit from the understanding of their elders, in a context that is not intimidating for teachers with a limited knowledge of Relativity. We should attempt to do the same with other areas of Mathematics and Physics so the next generation will have the benefit of what we have learned. This might

not be possible if we teach things solely from the bottom-up view. What if we had young people building Zome models[42] of E_8 instead? At least we need to give kids a chance to see what these figures look like, at Science Centers and Math Museums.

The nexus of Philosophy and Physics must be strong, for either topic to provide useful information. This means it is incumbent on the organizers of events and publications to provide a context for insightful contributions that forge a stronger connection between what appear to be separated views, or to push the envelope of developments on the outskirts. The 16th Marcel Grossmann conference was exemplary on both of these fronts, in its spirit of cooperation, openness, and inclusivity. The organizers deliberately included minority views and off-limits topics in both the choice of plenary speakers and in the various breakout sessions. So people were encouraged to look outside of their silos somewhat, and to explore what is beyond the island of comfortable mainstream assumptions. During MG16; a Philosophy of Physics approaching the ideal was observed. But in the world at large; there is a lot of progress to be made forging connections to support a higher ideal. What we see now is a world that largely ignores the advice of both philosophers and physicists, in favor of following popular icons. There is much to do, if we want the ideas that enlighten physicists to be meaningful for everyone, but things being discovered in Physics have a meaning that unavoidably affects all equally. There is no point to arguing Physics is devoid of meaning. Therefore our Philosophy must include the notion that Physics is relevant.

We owe much of our current understanding to the philosophers of ancient Greece, not least the notion of atomism with indivisibly small bits or increments in the cosmos or the way it is constructed, as was well-explained in Rovelli's book.[43] Leucippus likely brought the seed of this idea to Democritus from Anaximander's school. But we can see that atomism applied to Plato's comment that time is the projected image of eternity, shows up as every atom in the stream of Anaximander having a duration or persistence in time. This is observed as a half-life, when examining the same phenomenon in nuclear or sub-atomic Physics, due in part to the relativistic effects of time dilation. But here I note that parcels of space needed to have persistence in time already for those particles to exist. That is why it is important to continue our exploration of quantum gravity theories and try to understand the cosmological context for these theories in a broader way. So physicists should see it as a responsibility to build bridges between the philosophically disconnected islands of thought, by applying a Philosophy of Physics that supports our common endeavor to learn the secrets of the cosmos. Encouraging students as well as researchers to explore beyond what is known is important, and willingness to question our own boundaries is an important first step. We must be ready to leave the world of comfortable norms behind, when examining cosmic origins, to fully understand how things got to be the way they are now.

The broad debate on foundational issues in quantum mechanics, which took place at the famous 1957 Chapel Hill conference on *The Role of Gravitation in Physics*, is here critically analyzed with an emphasis on Richard Feynman's contributions. One of the most debated questions at Chapel Hill was whether the gravitational field had to be quantized and its possible role in wave function collapse. Feynman's arguments in favor of the quantization of the gravitational field, based essentially on a series of gedanken experiments, are here discussed. Then the related problem of the wave function collapse, for which Feynman hints to decoherence as a possible solution, is discussed. Finally, another topic is analyzed, concerning the role of the observer in a closed Universe. In this respect, Feynman's many-worlds characterization of Everett's approach at Chapel Hill is discussed, together with later contributions of his, including a kind of Schrödinger's cat paradox, which are scattered throughout the 1962-63 Lectures on Gravitation. Philosophical implications of Feynman's ideas in relation to foundational issues are also discussed.

Keywords: Gedanken experiment; Wave function collapse; Many-worlds.

1. Introduction: The Chapel Hill conference

Richard Feynman's most famous contribution in quantum theory is undoubtedly his celebrated path integral approach.[1] His contributions to the debate on interpretational issues are instead much less well known.[2,3] The first such contributions took place in the wide discussions which characterized the 1957 Chapel Hill conference,[4] whose title was: *The Role of Gravitation in Physics*. The Chapel Hill conference, which played a key role in triggering the so called *Renaissance* of general relativity[5] was of capital importance in establishing the future research lines in the field. Broadly, the main tracks were[6]: classical gravity, quantum gravity, and the classical and quantum theory of measurement (as a link between the previous two topics). In particular, foundational quantum issues were widely discussed by researchers attending the conference. The main motivation for addressing them came from the

fundamental question of whether the gravitational field had to be quantized, like other fundamental fields, or not. As its title declares, the ambitious goal of the conference was the merging of general relativity with the rest of physics and, especially, with the world of elementary particle physics, which was ruled by quantum mechanics, hence it was (and it still is, of course) very important to understand physics in regimes where both gravity and quantum mechanics become important. This was clearly stated by Peter G. Bergmann in the opening session of the second half of the conference, which was in fact focused on problems within the quantum domain (Ref. 4, p. 165):

> Physical nature is an organic whole, and various parts of physical theory must not be expected to endure in "peaceful coexistence." An attempt should be made to force separate branches of theory together to see if they can be made to merge, and if they cannot be united, to try to understand why they clash. Furthermore, a study should be made of the extent to which arguments based on the uncertainty principle force one to the conclusion that the gravitational field must be subject to quantum laws: (a) Can quantized elementary particles serve as sources for a classical field? (b) If the metric is unquantized, would this not in principle allow a precise determination of both the positions and velocities of the Schwarzschild singularities of these particles?

The answer to these questions was expected to lead to a novel perspective on the ordinary notions of space and time, by introducing uncertainty relations for quantities such as distances and volumes. Physicists hoped that, as a result, the divergences which plagued quantum field theory would get suppressed by the gravitational field. Along with the formal discussion on the main approaches to the quantization of the gravitational field (namely the canonical, the functional integral and the covariant perturbative approaches), which would have been developed in the following decades, a lot of time was devoted to conceptual issues, especially in discussion sessions. A broad debate arose on the problem of quantum measurement, the main conceptual question being:

> What are the limitations imposed by the quantum theory on the measurements of space-time distances and curvature? (Ref. 4, p. 167)

or, equivalently

> What are the quantum limitations imposed on the measurement of the gravitational mass of a material body, and, in particular, can the principle of equivalence be extended to elementary particles? (Ref. 4, p. 167)

As the editors of the written records of the conference[4] emphasized, an answer to the above questions could not be simply found in dimensional arguments, since the

Planck mass does not set a lower limit to the mass of a particle whose gravitational field can be measured. Indeed, a simple argument shows that the gravitational field of *any* mass can in principle be measured, thanks to the "long tail" of the Newtonian force law (Ref. 4, pp. 167-8).

The great part of the discussions of interest to us here developed in Section VIII of the conference (Ref. 4, pp. 243-60), where the focus was mainly on the contradictions eventually arising in the logical structure of quantum theory if gravity quantization is not assumed, but in fact many even more foundamental issues for quantum physics in general were touched as well. Feynman greatly contributed to these discussions, proposing several gedanken experiments in order to argue in favor of the necessity of gravitational quantization, and hinting to decoherence as a viable solution to the problem of wave function collapse. His contributions in fact triggered a wide debate on the quantum measurement problem and on the existence and meaning of macroscopic quantum superpositions. Further, in the subsequent session of the conference, which was the closing one (Ref. 4, pp. 263-278), he gave a "many-worlds" characterization of Hugh Everett III's relative state interpretation of quantum mechanics,[7] which had just been described for the first time by Everett's advisor, John A. Wheeler. It is interesting to notice that, in fact, the Chapel Hill conference was one of the few places where Feynman was directly involved in discussions about the foundations and interpretation of quantum mechanics.[2]

The Chapel Hill discussions played a pivotal role in triggering subsequent research on foundational issues, mainly on the quantum measurement problem and on the various possible interpretations of quantum mechanics, with an emphasis on the consequences of Everett's one. In this respect it is worth mentioning further contributions by Feynman, who despite not being often involved with foundational quantum issues, nonetheless kept thinking deeply on them also in the following years, especially when working on gravity, as hinted for example in a letter written in 1961 to Viktor Weisskopf[8]:

> How can we experimentally verify that these waves are quantized? Maybe they are not. Maybe gravity is a way that quantum mechanics fails at large distances.

as well as in several suggestions and considerations scattered throughout his 1962-63 graduate lectures on gravitation.[9]

In this paper, we historically and critically analyze Feynman's contributions to the debate about the foundations of quantum mechanics and gravity, with an emphasis on the Chapel Hill discussions, which constitute the main source about his thoughts on the matter. In particular, Section 2 deals with the problem of the quantization of the gravitational field while in Sections 3 and 4 the focus is on wave function collapse following a measurement and on Everett's relative state interpretation of quantum mechanics. Finally our concluding remarks are summarized in Section 5.

2. Quantization of the gravitational field: Gedanken experiments

In this Section we report on Feynman's arguments in favor of the quantization of the gravitational field. As a matter of fact, Feynman believed that nature cannot be half classical and half quantum and shared Bergmann's general ideas, as recalled by himself in some concluding remarks made at the end of the conference:

> The questions raised in the last three days have to do with the relation of gravity to the rest of physics. We have gravity - electrodynamics - quantum theory - nuclear physics - strange particles. The problem of physics is to put them all together. The original problem after the discovery of gravity was to put gravity and electrodynamics together since that was essentially all that was known. Therefore, we had the unified field theories. After quantum theory one tries to quantize gravity (Ref. 4, p. 272).

In particular, for Feynman gravity, like the other fundamental interaction that we experience at the macroscopic, classical level, i.e. electromagnetism, has a quantum foundation (see e.g. Refs. 10–12). Coherently with this, he developed an approach to quantum gravity (whose first hints were given at Chapel Hill, cf. Ref. 4, pp. 271-276) which was characterized by being fully quantum from the beginning.[9,13]

Feynman's arguments in favor of the quantization of gravity were totally different from the usual dimensional arguments, which rely on the assumption that gravity has to dominate over all other interactions at the Planck scale. According to him quantum effects involving gravity should be subject to probing without invoking such high scales. He provided further evidence to support this claim by putting forward thought experiments designed to show that, if quantum mechanics is required to hold for objects massive enough to produce a detectable gravitational field (the opposite would require a modification of quantum mechanics), then the gravitational field has to be quantized, in order to avoid contradictions. This view supported the hope that quantization of the metric would help taming the divergences present in quantum field theory and, in this way, it was relevant also for the theory of elementary particles. Let us thus retrace the discussion in more detail.

Section VIII began with Thomas Gold stating that, in the absence of phenomena not explainable by classical gravity, the only way to argue in favor of quantization of gravity is the presence of logical contradictions, of which he was not convinced (Ref. 4, pp. 243-244). Bryce S. DeWitt pointed out that difficulties may arise in the presence of quantized matter fields depending on the choice of the quantum expectation value of the stress-energy tensor as the source of the gravitational field (Ref. 4, p. 244). Indeed a measurement may change this expectation value, which implies a change of the gravitational field itself. The classical theory of gravitation is valid because fluctuations are negligible at the scale where gravitational effects become sizeable. At this point Feynman put forward his first thought experiment, which was a variant of the two-slit diffraction experiment, in which a mass indicator has been put behind the two-slit wall. Within a space-time region whose linear

dimensions are of order L in space and L/c in time, the uncertainty on the gravitational potential (divided by c^2 so that it is dimensionless and thus homogeneous to a metric) is in general $\Delta g = \sqrt{\frac{hG}{c^3L^2}} = \frac{L_P}{L}$, where $L_P = \sqrt{\frac{hG}{c^3}}$ is the Planck length.[a] The order of magnitude of the potential generated by a mass M within the spatial part of the considered region is $g = \frac{MG}{Lc^2}$, which implies $\Delta g = \frac{\Delta MG}{Lc^2}$. A comparison with the previous general expression gives a mass uncertainty $\Delta M = \frac{c^2 L_P}{G} \approx 10^{-5}$ grams, if the time of observations is less than L/c. On the other side, by allowing an infinite time, M would be obtained with infinite accuracy. This option, according to Feynman, could not take place for a mass M fed into the two-slit apparatus, so that the apparatus will not be able to uncover the difficulty unless M is at least of order 10^{-5} grams. Thus he concluded that

> Either gravity must be quantized because a logical difficulty would arise if one did the experiment with a mass of order 10^{-4} grams, or else [...] quantum mechanics fails with masses as big as 10^{-5} grams (Ref. 4, p. 245).

Subsequent discussions moved on more formal matters such as the meaning of the equivalence principle in quantum gravity, with Feynman contrasting Helmut Salecker's suggestion of a possible violation of the equivalence principle in the quantum realm. Then a further remark by Salecker himself brought the participants' attention back to the topical issue, the necessity of gravitational quantization. In particular, as explained by an Editor's note (see Ref. 4, p. 249), Salecker hinted to the possibility to build up an action-at-a-distance theory of gravitation in whole analogy to the electromagnetic case, with charged quantized particles acting as a source of a unquantized Coulomb field. At this stage Frederik J. Belinfante proposed the quantization of both the static part and the transverse part of the gravitational field (the last one describing gravitational radiation) as a way to circumvent difficulties related to the choice of the expectation value of the stress energy tensor as the source of the gravitational field. As noticed by Zeh,[2] Belinfante's proposal reflects his ideas on the ontology of quantum mechanics, which point toward an epistemic rather than ontic interpretation of the wave function:

> "There are two quantities which are involved in the description of any quantized physical system. One of them gives information about the general dynamical behavior of the system, and is represented by a certain operator (or operators). The other gives information about our knowledge of the system; it is the state vector [...] the state vector can undergo a sudden change if one makes an experiment on the system. The laws of nature therefore unfold continuously only as long as the observer does not bring extra knowledge of his own into the picture." (Ref. 4, p. 250).

[a] This follows from an argument given by Wheeler in Ref. 4, pp. 179-180, involving a path integral for the gravitational field.

Belinfante's description used the Heisenberg picture, at variance with Feynman who reasoned in terms of wave functions as dynamical objects. Indeed, according to Belinfante "the wave function [...] must change for reasons beyond the system's physical dynamics. He does not refer to ensembles of wave functions or a density matrix in order to represent incomplete knowledge" (Ref. 2, p. 65).

Feynman promptly replied with his second gedanken experiment, a Stern-Gerlach experiment with a gravitational apparatus. More in detail, he considered a spin-1/2 particle going through a Stern-Gerlach apparatus and then crossing the first or the second of two counters (denoted as 1 and 2, respectively), each one connected by means of a rod to an indicator. He took the indicator as a little ball with a diameter of 1 cm, going up or down depending on the position of the object, at counter 1 or 2, respectively. Quantum mechanics, as underlined by Feynman, provides in principle an amplitude for the ball up and an amplitude for the ball down[b]. However, the ball is chosen to be macroscopic, so as to be able to produce a detectable gravitational field, which in turn can move a probe ball. In other words a channel between the object and the observer is established via the gravitational field. This ideal experiment led Feynman to infer the following conclusion about gravity quantization:

> Therefore, there must be an amplitude for the gravitational field, provided that the amplification necessary to reach a mass which can produce a gravitational field big enough to serve as a link in the chain does not destroy the possibility of keeping quantum mechanics all the way. There is a bare possibility (which I shouldn't mention!) that quantum mechanics fails and becomes classical again when the amplification gets far enough, because of some minimum amplification which you can get across such a chain. But aside from that possibility, if you believe in quantum mechanics up to any level then you have to believe in gravitational quantization in order to describe this experiment (Ref. 4, p. 251).

A subsequent answer to a question by Hermann Bondi[c] further highlighted, according to Zeh (Ref. 2 p. 67), Feynman's position against the epistemic interpretation of the wave function:

> I don't really have to measure whether the particle is here or there. I can do something else: I can put an inverse Stern-Gerlach experiment on and bring the beams back together again. And if I do it with great precision, then I arrive at a situation which is not derivable simply from the information that there is a 50 percent probability of being here and a 50 percent probability of

[b] Zeh[2] points out how Feynman's description of the measurement process is very close to the standard measurement and registration device proposal by John von Neumann.[14]

[c] "What is the difference between this and people playing dice, so that the ball goes one way or the other according to whether they throw a six or not?" (Ref. 4, p. 252).

> being there. In other words, the situation at this stage is not 50-50 that the die is up or down, but *there is an amplitude* that it is up and an amplitude that it is down – a complex amplitude – and as long as it is still possible to put those amplitudes together for interference you have to keep quantum mechanics in the picture. (Ref. 4, p. 252, our emphasis)

3. Wave function collapse

The aim of this Section is to highlight Feynman's ideas about the quantum measurement problem. Indeed, from the last sentence of the last quote, one can infer a clear reference to the problem of wave function collapse, as well as a hint to decoherence as a possible solution. A further suggestion can be found in a subsequent remark:

> Well, it's a question of what goes on at the level where the ball flips one way or the other. In the amplifying apparatus there's already an uncertainty - loss of electrons in the amplifier, noise, etc. - so that by this stage the information is completely determined. Then it's a die argument. You might argue this way: Somewhere in your apparatus this idea of amplitude has been lost. You don't need it any more, so you drop it. The wave packet would be reduced (or something). Even though you don't know where it's reduced, it's reduced. And then you can't do an experiment which distinguishes *interfering* alternatives from just plain odds (like with dice). (Ref. 4, p. 252, our emphasis)

According to Feynman, wave packet reduction occurs somewhere in his experimental apparatus thanks to the amplifying mechanism, so that a huge amount of amplification (via the macroscopic gravitational field of the ball) may be effective in changing amplitudes to probabilities. Then he wondered about the possibility to devise an experiment able in principle to avoid the wave packet reduction due to the amplification process. Subsequent criticism by Leon Rosenfeld and Bondi further stimulated Feynman's intuition. So he was led to envisage a sort of quantum interference in his experiment, driven by the gravitational interaction between macroscopic balls, which could be described by means of a quantum field with suitable amplitudes taking a value or another value, or to propagate here and there. But, as Bondi suggested, any irreversible element should be removed, such as for instance the possibility of gravitational links to radiate. Probably, this is another point in which a further hint to the role of decoherence in destroying quantum interference can be recognized, even if in Bondi's and Feynman's words a reference is made only to classical irreversibility.[2] In fact the meaning of decoherence, its origin and its role in smearing out phase relations as well as in triggering the transition to classicality, were still unclear in the late 1950s[d]. The discussion went on with Feynman arguing that quantum interference might eventually take place with a mass of macroscopic

[d]For a historical and research account on decoherence, see Ref. 15 and references therein.

size, say about 10^{-5} gram or 1 gram, and hinting to the possible role of gravity in destroying quantum superpositions. In his words:

> There would be a *new principle*! It would be *fundamental*! The principle would be: – *roughly*: *Any piece of equipment able to amplify by such and such a factor* (10^{-5} grams or whatever it is) *necessarily must be of such a nature that it is irreversible.* It might be true! But at least it would be fundamental because it would be a new principle. There are two possibilities. Either this principle – this missing principle – is right, *or* you can amplify to any level and still maintain interference, in which case it's absolutely imperative that the gravitational field be quantized... *I believe*! *or* there's another possibility which I have't thought of (Ref. 4, pp. 254-255, emphasis in original).

The same ideas would have been pursued later by Feynman in his Lectures on Gravitation,[9] where he considered "philosophical problems in quantizing macroscopic objects" and hinted to the possibility of a failure of quantum mechanics induced by gravity:

> I would like to suggest that it is possible that quantum mechanics fails at large distances and for large objects. Now, mind you, I do not say that I think that quantum mechanics *does* fail at large distances, I only say that it is not inconsistent with what we do know. If this failure of quantum mechanics is connected with gravity, we might speculatively expect this to happen for masses such that $\frac{GM^2}{\hbar c} = 1$, of M near 10^{-5} grams, which corresponds to some 10^{18} particles (Ref. 9, pp. 12-13).

Within the same set of lectures (Ref. 9, p. 14), the possibility is recognized that amplitudes may reduce to probabilities for a sufficiently complex object, thanks to a smearing effect on the evolution of the phases of all parts of the object. Such a smearing effect could have a gravitational origin. A similar idea is expressed in the end of the letter to Weisskopf,[8] as already mentioned in the Introduction. This shows how Feynman was open-minded with respect to all possibilities, despite his strong belief in the quantum nature of reality.

The debate on gravity quantization here highlighted and, in particular, Feynman's deep insights, triggered subsequent research on the possibility of a gravity-induced collapse of wave function, as a viable solution to the measurement problem in quantum mechanics.[16–25] The idea is attractive since gravity is ubiquitous in nature, and gravitational effects depend on the size of objects, so it has been greatly developed in the subsequent years up to the present day. Along this line of thinking, Roger Penrose suggested that a conflict emerges when a balanced superposition of two separate wave packets representing two different position of a massive object is considered.[22,23] In his words (see Ref. 26, p. 475): "My own point of view is that as soon as a *significant* amount of space-time curvature is introduced, the rules of quantum linear superposition must fail". Clearly the conflict is the result of putting

together the general covariance of general relativity and the quantum mechanical superposition principle. By assuming in each space-time the validity of the notions of stationarity and energy, and by taking the difference between the identified time-translation operators as a measure of the ill-definiteness of the final superposition's energy, the decay time for the balanced superposition of two mass distributions can be estimated:

$$t_D = \frac{\hbar}{\Delta E_{grav}}. \tag{1}$$

Here ΔE_{grav} is the gravitational self-energy of the difference between the mass distributions of each of the two locations of the object. This means that massive superpositions would immediately undergo collapse. The same idea led Penrose to introduce the so called Schrödinger-Newton equation,[24] which governs a peculiar non-linear evolution of the center-of-mass wave function. Its soliton-like dynamics is the result of a competition between a partial shrinking due to the non-linear term and a partial spreading due to the usual dynamical term.

More recently, other collapse models(called *dynamical* collapse models) have been put forward,[27–30] where the collapse of the wave function is induced by a different mechanism, i.e. the interaction with a random source such as an external noise source.

From the experimental side, a lot of proposals have been made as well, mainly aimed to explore a parameter range where both quantum mechanics and gravity are significant. For instance it has been possible to create a quantum superposition state with complex organic molecules with masses of the order $m = 10^{-22}$ kg.[31,32] Recent experimental proposals involve matter-wave interferometers,[33–35] quantum optomechanics[36–39] and magnetomechanics.[40] Today a major challenge is, on one hand, to design viable experiments at the interface between the quantum and classical worlds, while on the other hand to reveal and discriminate gravity-induced decoherence from environmental decoherence in such experiments. However, despite such a huge theoretical and experimental effort, a definite answer to the quantum measurement problem as well as to the problem of the emergence of classical from the quantum world is still lacking.

4. The role of the observer in a closed Universe

In this Section we deal with the issue of the role of the observer in a closed Universe, as emerged from discussions carried out in the closing session of Chapel Hill conference. Here Wheeler gave the first public presentation of Everett's relative-state interpretation of quantum mechanics,[7,41] as follows:

> General relativity, however, includes the space as an integral part of the physics and it is impossible to get outside of space to observe the physics. Another important thought is that the concept of eigenstates of the total

> energy is meaningless for a closed Universe. However, there exists the proposal that there is one "universal wave function". This function has already been discussed by Everett, and it might be easier to look for this "universal wave function" than to look for all the propagators (Ref. 4, p. 270).

Feynman promptly replied by characterizing of Everett's approach as "many-worlds":

> The concept of a "universal wave function" has serious conceptual difficulties. This is so since this function must contain amplitudes for all possible worlds depending on all quantum-mechanical possibilities in the past and thus one is forced to believe in the equal reality of an infinity of possible worlds (Ref. 4, p. 270).

The same idea will be presented some years later in the Lectures on Gravitation (Ref. 9, pp. 13-14), where Feynman also discussed the role of the observer in quantum mechanics. The Schrödinger's cat paradox allowed him to illustrate the difference between the results of a measurement carried out by an external as well as an internal observer. While the external observer describes his results by an amplitude, with the system collapsing into a well-defined final state after the measurement, according to the internal observer the results of the same measurement are given by a probability. Clearly the absence of an external observer leads to a paradox, which is much more effective when considering the whole Universe as described by a complete wave function. This Universe wave function is governed by a Schrödinger equation and implies the presence of an infinite number of amplitudes, which bifurcate from each atomic event. In other words, according to Feynman, the Universe is constantly spitting into an infinite number of branches, as a result of the interactions between its components. Here the key observation is that interactions play the role of measurements. As a consequence, an inside observer knows which branch the world has taken, so that he can follow the track of his past. Feynman's conclusion brings into play a conceptual problem:

> Now, the philosophical question before us is, when we make an observation of our track in the past, does the result of our observation become real in the same sense that the final state would be defined if an outside observer were to make the observation (Ref. 9, p. 14)?

A further discussion of the meaning of the wave function of the Universe is carried out later in the Lectures on Gravitation (Ref. 9, pp. 21-22). Here Feynman restated his "many-worlds" characterization of Everett's approach with reference to a "cat paradox on a large scale", from which our world eventually could be obtained by a "reduction of the wave packet". Concerning this reduction, he wondered about the relation between Everett's approach and collapse mechanisms of whatever origin. Perhaps it may be relevant to quote a comment by John P. Preskill, within a talk

about the Feynman legacy, given at the APS April Meeting (cf. Ref. 42, slide 29):

> When pressed, Feynman would support the Everett viewpoint, that all phenomena (including measurement) are encompassed by unitary evolution alone. According to Gell-Mann, both he and Feynman already held this view by the early 1960s, without being aware of Everett's work[e]. However, in 1981 Feynman says of the many-worlds picture: "It's possible, but I am not very happy with it".

Historically, Everett's proposal[7] was the first attempt to go beyond the Copenhagen interpretation in order to apply quantum mechanics to the Universe as a whole. To this end, the well known separation of the world into "observer" and "observed" has to be superseded by promoting the observer to be part of the system, while the usual quantum rules are still effective in measuring, recording or doing whatever operation. Quantum fluctuations of space-time in the very early Universe have also to be properly taken into account. On the other hand, this proposal lacks an adequate description of the origin of the quasi-classical realm as well as a clear explanation of the meaning of the branching of the wave function.

Everett's work has been further developed by many authors[43–48] and its more recent generalization is known as *decoherent histories approach to quantum mechanics of closed systems*. A characterizing feature of this formulation is that neither observers nor their measurements play a prominent role. Furthermore the so called *retrodiction*, namely the ability to construct a history of the evolution of the Universe towards its actual state by using today's data and an initial quantum state, is allowed. The process of prediction requires to select out decoherent sets of histories of the Universe as a closed system, while decoherence in this context plays the same role of a measurement within the Copenhagen interpretation. Decoherence is a much more observer-independent concept and gives a clear meaning to Everett's branches, the main issue being to identify mechanisms responsible for it. In particular, it has been shown that decoherence is frequent in the Universe for histories of variables such as the center of mass positions of massive bodies.[49]

5. Concluding remarks

In this paper we have retraced Feynman's thoughts on foundational issues in quantum mechanics. Such ideas were rarely expressed by him, who mainly linked his name to his masterful application of thus theory, but they clearly emerged whenever he focused on the problem the interface of quantum mechanics and gravity, with the ensuing great conceptual questions. These problems, such as that of the collapse of the wave function, of macroscopic superpositions and of observers which are parts of the observed system itself, are of course not limited to the gravitational

[e]We do not agree that Feynman was not aware of Everett's work in the 1960s, since he commented on it at Chapel Hill in 1957.

realm, but lie at the very heart of quantum physics. Despite much progress having been achieved since Feynman's times, part of which had been anticipated by him and other participants to the Chapel Hill conference, much work still needs to be done, before his most famous remark[50] "I think I can say that nobody understands Quantum Mechanics" can be considered to be no longer true.

Summary of the parallel session HR3

Shokoufe Faraji

University of Bremen, Center of Applied Space Technology and Microgravity (ZARM), 28359 Germany

This is the summary of the parallel session entitled "Time and Philosophy in Physics", chaired by Shokoufe Faraji in the sixteenth Marcel Grossmann Meeting. This parallel session aimed to discuss open issues related to Time and fundamental laws from different perspectives in a complementary point of view.

Keywords: Time in Physics, Time in Philosophy; passage of Time; fundamental laws

1. Introduction

It is astonishing that we can understand the Universe in the way we study it. However, concurrently celebrating the achievements of science, we should respect its limits and not claim more than it can actually achieve or attain, where by pushing its limits, complex philosophical issues may arise. However, the concern is about when theories are applied beyond their range of applicability. Since the visible Universe may not give us enough information to characterize the laws of physics completely, thus we need a more comprehensive framework that not only incorporates science but can also go beyond the limits.

Therefore, for example the questions on the domain of validity of the fundamental laws of physics and the nature of existence of infinities are sound viable. However, maybe above all, the nature of Time and the order present in nature is the greatest secret in the Universe.[1–5]

2. The passage of Time and top-down causation

This is reported by Prof. Barbara Drossel.

There is a common underlying agreement among many physicists to consider the properties of the fundamental equations of physics are also properties of nature. Therefore, since these equations are deterministic, it is concluded that nature is also deterministic. Besides, the Time evolution is completely determined by the initial state and the fundamental laws. Furthermore, these laws are invariant under changing the direction of Time. However, any physical theory is an approximation and not an exact description of the physical processes of interest. And by no means it is a complete description of everything that is going on in the physical world. Even a deterministic and Time-reversible fundamental theory is in practice supplemented by irreversible and stochastic features. In conclusion, the irreversibility and stochasticity enter when the influence of the environment on a system is taken into

account, which is related to emergence and top-down causation and microsystems are causally open to influences from the macroscopic environment.

3. Temporal asymmetry and causality

This is reported by Prof. Wayne Myrvold.

The temporal asymmetry between past and future permeates virtually every aspect of the world of our experience. As far as we know, it has no counterpart in the laws of fundamental physics. One option is to trace this asymmetry to a fact about the early state of the universe, either taken as a contingent, unexplained fact, or as a consequence of some physical principle. However, there is an alternate route to explaining temporally asymmetric phenomena, according to how work on the process of equilibration is done. This does not involve any hypothesis about the past, rather it is founded on conditions that we can apply at any Time, closely related to the concept of causality.[6] In fact, temporal asymmetry enters our explanations because the very notion of what it means to explain something is temporal asymmetry. To sum up, the conceptions of casual order and temporal order are not independent and in fact they are two sides of the same coin.

Therefore, the absence of temporally asymmetry in the fundamental laws is no obstacle to explaining that asymmetry. What is invoked is a temporal asymmetry in the very notion of explanation.

4. Temporal ordering in Philosophy and Physics

This is reported by Prof. Norman Sieroka.

Time and temporal order are one of the oldest and most eminent concepts in both philosophy and physics. One of the main aims of philosophy is to coordinate the human experience in structural analysis and comparison. For this, one needs to acknowledge the differences in types of Time and Time scales. Then we realize many issues about Time are issues about the ordering of events both within and across different types and scales.[7]

From the philosophical point of view, mainly there are two different types of temporal orderings. The first one, the presentism or possibilism perspective; events being characterized by the present, past or future, and try to focus on mental states and experience; however, this view may have trouble in physics if simultaneity is not absolute. The second view is Eternalism; the ordering relation is only about events being earlier or later and focuses on physical states, and there is no vital distinction between past, present and future. However, it seems the second one to be of importance to physics.

To sum up, the relation between these two orderings and their inner dynamics can be interesting in the context of the interaction between philosophy and physics. Besides, investigation of the notion of an *event* seems fundamentally essential in both areas.

5. Time in Quantum Gravity: A false problem

This is reported by Prof. Carlo Rovelli.

There are several problems of Time in Physics that are related to each other. Indeed, always a lot of confusion comes from mixing problems that are distinct one from another. In particular, an extensive discussion of Time in Quantum Gravity was caused in the 60th by the Wheeler-de Witt equation, which at first sight suggests Time is frozen and there is no evolution. However, dealing with Time in General Relativity is a slightly different than in non-relativistic Physics.[8] The difficulty for developing Time in General Relativity is to struggle with the meaning of the coordinates. In fact, coordinates in non-relativistic field Theory are measurable by rods and clocks; in contrast to General Relativity, there is nothing physical attached to coordinates. In fact, all possible versions of Time in General Relativity is a quantity that is locally dependent on the Gravitational field. This means the entire formulation of dynamics as evolution in Time does not fit within the scope of General Relativity. In fact, instead of conceptualizing the evolution of physical variables evolving with respect to a variable, we are forced to consider the evolution of a variable with respect to one another. So by this perception, the relativistic dynamics is not frozen in Quantum Gravity and simply described in a different language. Thus, we can predict the relation among a number of variables, and there is no mystery about *emergence of Time* in Quantum Gravity. In fact, many tentative quantum gravity theories, from the Wheeler-de Witt equation to Loop Quantum Gravity, do not specify a Time variable, and yet they are predictive. Of course, this view has substantial consequences, for example, there are some indications that the Time might be discrete.

6. The issue of Time in Fundamental Physics

This is reported by Prof. Abhay Ashtekar.

The Notion of Time in fundamental physics has undergone radical revisions over centuries dramatically.[9] However, new observational windows continually open up in the process. In particular, issues at the forefront of cosmology and quantum gravity pose new conceptual and technical challenges. The same is true in particle Physics, GPS systems or Quantum Information Theory.

A pleasing feature is coming together from physical and operational ideas, fundamental concepts from General Relativity, the associated Hamiltonian constraint, and a post-Pauli understanding of how one should think of Time in Quantum Mechanics. In fact, in Quantum Mechanics, the focus is on the extended system by considering the clock. In Quantum Gravity, there is no such thing as Time in Quantum mechanics, and the extended system kinematics is already contained the dynamical variables of General Relativity.

However, it does not mean *everything is understood and well-controlled.* Many refinements, extensions and technical issues are still open; however, there is no conceptual roadblock to this understanding.

7. Time in General Relativity and Quantum Mechanics

This is reported by Prof. Claus Laemmerzahl.

The nature of Time is characteristic of the underlying theory. Within the formalism of General Relativity, it is possible to define or characterize a distinguished clock and Time operationally, and this is the so-called standard clock providing proper Time. In addition, within Quantum Mechanics, it is possible to define a clock and the corresponding Time. This clock is an atomic clock, and it provides Time in the unit of the second. It can be proven with high precision that both clocks are compatible though they are based on entirely different notions.[10] Based on such standard clocks, we define Special Relativity effects such as the gravitational redshift, gravitational Time delay and gravitomagnetic clock effect. This compatibility breaks down in strong gravitational fields and also in generalized theories of gravity.

It would be of some interest to study the relativistic two-body problem and another Time scale from chirp. In addition, studying a bound system in an external gravitational field like the Earth-Moon system in the field of the Sun, seems necessary to our understanding.

8. Time's passage

This is reported by Janathan Dickau.

The way we experience Time is in the accumulation of experiences and events that happen in the moment. On the one hand, philosophers have tried to explain both the nature of Time and its origin. On the other hand, the meaning of Time in different areas of physics like in Classical and Quantum Mechanics, and Relativity are different. So we hope for example Quantum Gravity theories will help resolve this issue. Recent advances in Mathematics also hold promise for a unified basis explaining both the thermodynamic and quantum-mechanical Time arrows in a consistent way. It is important to continue our exploration of quantum gravity theories and try to understand the cosmological context for these theories in a broader way. So physicists should see it as a responsibility to build bridges between the philosophically disconnected islands of thought, by applying a Philosophy of Physics that supports our common endeavor to learn the secrets of the cosmos.

9. A glimpse of Feynman's contributions to the debate on the Foundations of Quantum Mechanics

This is reported by Dr. Adele Naddeo.

One of the most debated questions in the famous 1957 Chapel Hill conference on "The Role of Gravitation in Physics" was whether or not the gravitational field has to be quantized.[11] Feynman proposed several gedanken experiments in order to argue in favor of the necessity of gravitational quantization, and hinting to decoherence as a viable solution to the problem of wave function collapse.[12] Feynman believed that nature cannot be half classical and half quantum; therefore, we had the unified field theories. After quantum theory one tries to quantize gravity!

Another issue was related to the limitations that quantum quantum theory may impose on the measurements of space-time distances and curvature. However, since the Planck mass does not set a lower limit to the mass of a particle whose gravitational field can be measured, so the gravitational field of any mass can in principle be measured.

Feynman also discussed the role of the observer in quantum mechanics. The Schrödinger's cat paradox allowed him to illustrate the difference between the results of a measurement carried out by an external as well as an internal observer.[13] While the external observer describes his results by an amplitude, according to the internal observer the results of the same measurement are given by a probability. In other words, according to Feynman, the Universe is constantly spitting into an infinite number of branches, as a result of the interactions between its components. As a consequence, an inside observer knows which branch the world has taken, so that he can follow the track of his past. However, in 1981 Feynman says of the many-worlds picture: *It's possible, but I am not very happy with it.*

10. Conclusion

Physics enables everything and underlies everything, but it does not mean it determines everything.[5] Perhaps the world is much more complicated than can be explained only by science. Thus, we should trust our most immediate experiences, new conceptual and technical challenges. In fact, they are the basis and guides for being capable of thinking and acting. Based on these, we could critically examine and take care of metaphysical claims and our ultimate questions like: does the world covered by science describe the whole reality? What about underlying assumptions and axioms in cosmology? What about all the philosophical issues related to "the interpretation of quantum mechanics," "measurement Problem," and the ontological character of quantum states? Why does the Universe have such a unique structure that life can exist?

We review the two-families scenario of compact stars. Under the hypothesis that strange quark matter is the ground state of dense matter one can infer the existence of two separated branches of stars: hadronic stars and quark stars. While the first branch is populated by very compact and light stars, the second branch can be populated by very massive stellar objects. A possible confirm to this scenario derives from the gravitational waves detections GW170817 and GW190814, the first one suggesting the existence of stars with radii as small as 11km for $M \sim 1.4 M_\odot$ and the second one suggesting the existence of a compact star with a mass above $2.5 M_\odot$.

Keywords: Compact stars, Binary mergers

1. Introduction

The opening of the Gravitational Waves (GWs) astronomy has already led to some important and new measurements of the structure of neutron stars (NSs) and constraints on the population and mass distribution of neutron stars binaries[1] and neutron star - black hole (BH) binaries.[2] There are two merger events on which we want to focus here: GW170817[3] and GW190814.[4] The first one has being unambiguously associated to a NS-NS merger and it is the first example of multimessenger astronomy since, in this case, also the electromagnetic counterparts GRB170817A and AT2017gfo have been detected. With a total mass of $2.74 M_\odot$, this event is associated to the merger of two NSs with a mass around $1.37 M_\odot$ and thus far below the two solar mass limit observed through pulsar timing measurements, see e.g.[5]. Interestingly by combining the constraints on the tidal deformability obtained from the GW signal and the properties of the electromagnetic signals, a precious constraint on the structure of NSs has been found: the radius of the $1.4 M_\odot$ mass NS $R_{1.4} = 11.0^{+0.9}_{-0.6}$km at 90% credible interval.[6] Such a small radius suggests a quite soft equation of state for dense nucleonic matter and one can predict a maximum mass $m_{\rm max}$ value of $\sim 2.3 M_\odot$.

On the other hand, GW190814 has been produced by the merger of a $23 M_\odot$ BH and a compact object with mass in the range $2.5 - 2.67 M_\odot$. The nature of the low mass companion is unclear, it could be the lightest BH or the heaviest NS ever discovered. By assuming that it is indeed a NS, one would get a very strong

constraint on the equation of state: only very stiff equations of state could lead to such massive compact stars, see e.g.[7]. Thus, a tension emerges between the constraints obtained from GW170817 and GW190814.

The two-families scenario[8–14] proposes a solution to this tension based on the hypothesis of coexistence of hadronic stars (HS) and quark stars (QS) the first being very compact and the second being very massive. In the following we will review this scenario outlining the differences with respect to the standard one family scenario and other astrophysical scenarios with two separated branches of compact stars.

2. Modelling the equation of state and structure of compact stars

The equation of state of dense matter is rather uncertain and indeed NSs are considered in nuclear and particle physics as natural laboratories for matter at extremely high densities, order of ten times the nuclear saturation density n_s. There are however a few theoretical arguments that suggest, qualitatively, what could happen if matter is compressed (in NSs by gravity) above n_s. First, the increase of the baryon chemical potential must lead, at some unknown density, to the appearance of new baryons, namely hyperons or delta resonances. The appearance of new degrees of freedom is necessary accompanied by a softening of the equation of state. The value of the threshold density for the emergence of these degrees of freedom and how much the equation of state is softened due to their appearance depend on the details of the theoretical modelling of the equation of state. With the present knowledge one cannot exclude that NSs in which also hyperons and delta resonance (called hadronic stars, HSs) form could be as massive as $2M_\odot$, see for instance[15] where also kaon condensates are considered in the computation of the equation of state. If the maximum mass of NSs $M_{max} \sim 2.6M_\odot$, it is difficult to explain such a massive object in terms of a HS (at the moment there are no calculations showing that HS could be so massive). Thus, the threshold for the formation of hyperons and delta would be above the central density n_c reached in NSs. For $m_{\rm max} = 2.6M_\odot$ it has been found in[16] that $n_c \leq 4.5n_s$, one would thus conclude that no new degrees of freedom are produced up to $4.5n_s$. Such a possibility could be realised if an extremely strong hyperon-hyperon repulsion is assumed as e.g. in the calculations of.[17] Here we will adopt the most common result that hyperons and/or delta resonance appear in dense matter already at about twice n_s.[18] The resulting softening, if no ad hoc repulsion term between hyperons is added (see e.g.[19]), is such that M_{max} for HSs could be as low as $1.6M_\odot$. Moreover radii as small as 10km are obtained for the most massive configurations. Thus very compact objects are interpreted as being HSs, we will discuss one example of mass-radius relation within this scenario later on.

How to explain then the existence of massive NSs, with masses possibly as high as $2.6M_\odot$? Since in the two-families scenario massive stars are QSs, the equation of state of quark matter must be rather stiff. Let us consider the simple constant speed of sound (CSS) equation of state for which the pressure p and the energy

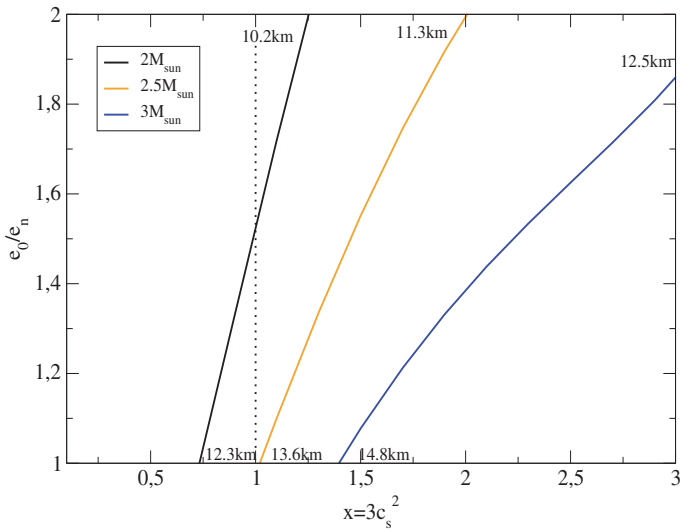

Fig. 1. Lines of constant $m_{\max}$ in the $e_0 - x$ plane. The vertical dashed line indicates the conformal limit, $c_s^2 = 1/3$.

density e are related by the relation: $p = c_s^2(e - e_0)$ where e_0 is the energy density at zero pressure and c_s is the (constant) speed of sound. The stiffness is regulated by e_0 and c_s: the larger the value of c_s and/or the smaller the value of e_0, the stiffer the equation of state. Indeed, by solving the TOV equations by adopting such an equation of state one can show, through numerical calculations, that $m_{\max}$ as function of e_0 and c_s can be described by the following parametrization: $m_{max}(x, e_0) = (e_s/e_0)^{1/2}(0.11 + 3.27x - 1.04x^2 + 0.13x^3)$ where $x = c_s^2/(1/3)$ and e_s is the energy density of nuclear matter $e_s \sim 150$ MeV/fm^3, see.[20] For c_s the upper bound is 1, namely the causal limit whereas the lower bound for e_0 can be taken at $e_0 = e_s$, namely by assuming that strange quark matter has an energy density at $p = 0$ not smaller than the one of nuclear matter.

In Fig. 1 we display the constant maximum mass curves in the x - e_0 plane. As one can notice, if one sets $c_s = 1/3$, namely to its asymptotic value as predicted by perturbative QCD (the so called conformal limit), one can reach values for $m_{\max}$ as high as $\sim 2.5 M_\odot$ if e_0 is set to e_s. Thus for $c_s = 1/3$ one could touch the lower limit for the low mass companion of GW190814. Small deviations from the conformal limit would allow to easily reach its upper limit, namely $2.67 M_\odot$. It is interesting to also discuss the radii of massive compact stars. For a fixed value of maximum mass, the radius of $m_{\max}$ decreases for increasing values of c_s (and e_0). For instance for $m_{\max} = 2M_\odot$, $r_{\max}$ ranges from 12.3km (for $x = 0.7$) to 10.2 (for $x = 1.2$) km. Interestingly, the analysis of the NICER data on PSR J0740+6620, provides $R = 12.35 \pm 0.75$ km for $M = 2.08 \pm 0.07 M_\odot$.[21] In our scenario, and under the hypothesis that $m_{\max}$ is actually $\sim 2M_\odot$, one would infer that c_s needs to be close to the conformal limit in order to explain the radius of PSR J0740+6620.

This is at odd with the so-called twin-stars scenario where a strong first order phase transition is assumed to occur from nucleonic matter to quark matter. The necessary softening associated with the phase transition must be compensated by large values of c_s ($c_s \sim 1$) in order to explain the existence of massive stars, see e.g.[22].

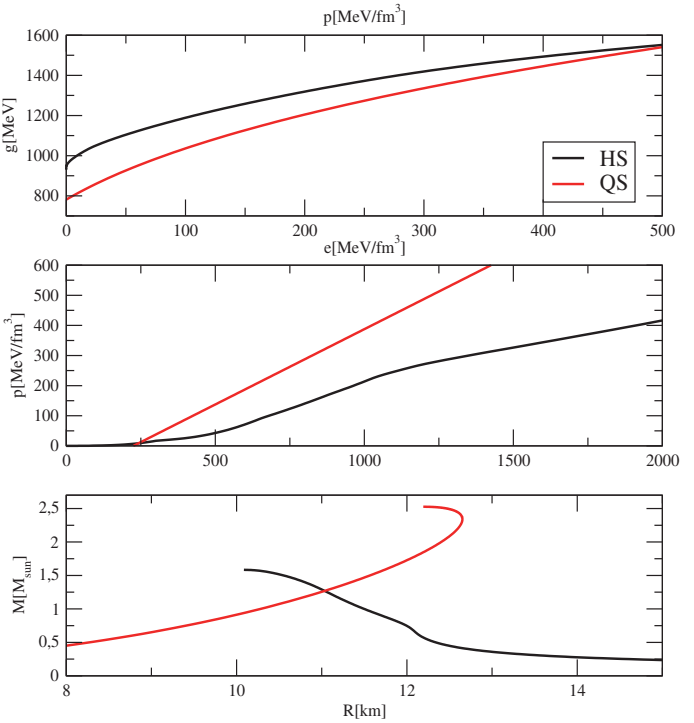

Fig. 2. Upper panel: Gibbs potential g as a function of the pressure for hadronic and quark matter. The phase with the lowest g is thermodynamically preferred. Middle panel: relation between pressure and energy density for hadronic and quark matter. Lower panel: mass-radius relations for HSs and QSs.

An important point when discussing the possibility of separated branches of compact stars is the thermodynamical consistency of the equations of state. In the two-families scenario, the branch of QSs is populated via the conversion of a HS. The conversion itself, to start, needs a specific condition on the thermodynamical variable of the two phases, namely at the same pressure (and same temperature) the new phase must have a smaller Gibbs potential according to the second principle of thermodynamics. To compute the Gibbs potential $g = (e + p)/n$ we need to first compute the baryon density in the CSS model as a function of the pressure. By using the relation $p = n^2 \frac{\partial(e/n)}{\partial n}$ one can show that:

$$n = n_0 \left(\frac{p(1 + c_s^2) + c_s^2 e_0}{c_s^2 e_0} \right)^{\frac{1}{1+c_s^2}} \tag{1}$$

where n_0 is the baryon density at zero pressure. In Fig. 2, upper panel we show the comparison between the Gibbs potential of a hadronic equation of state, SFHo-HD taken from[13] and a CCS equation of state of quark matter with $c_s^2 = 0.5$, $e_0 = 1.5e_s$ and $n_0 = 1.8n_s$. The Gibbs potential of the quark phase is below the one of the hadronic phase at least up to very large values of the pressures (~ 500 MeV/fm^3) that are not reached within the HSs branch (for which the maximum central pressure is ~ 330 MeV/fm^3 for this specific example). This means that quark matter can be nucleated from hadronic matter, the only necessary condition being the amount of strangeness in the hadronic phase. In,[13] we have estimated that the critical mass of HSs allowing for nucleation varies in the range $1.5 - 1.6M_\odot$. In the middle panel of Fig. 2, we display the relation between pressure and energy density for the two equations of state. One can notice that the quark matter equation of state is stiffer in the $p - e$ plane and thus leads to larger maximum masses. Although the quark equation of state is stiffer than the hadronic one, is anyway preferred (once the nucleation and the conversion process start) due to its smaller Gibbs potential. Finally in the lower panel, we display the mass radius curve of HSs and QSs. In this specific example, the quark equation of state leads to a maximum mass of $2.5M_\odot$ and this could potentially explain the nature of the low mass companion of GW190814 as being a QS. At the same time, the HSs branch is populated by very compact stars, as small as 10km. The event GW170817 is interpreted in our scenario as a merger of a HS and a QS. The computed average tidal deformability, $\tilde{\Lambda}$, is in agreement with the constraints obtained from the GW signal, see.[13]

3. Conclusions

We have reviewed the two-families scenario proposed in.[8] In this scenario two brances of compact stars exist, HSs which could be very compact and QSs which could be very massive. This scenario can therefore explain why certain sets of data (both on GW and EM signals) suggest small radii ($R < 11$km) and other sets of data suggest large masses, as large as $2.5M_\odot$. The coexistence of these branches is possible because the quark matter equation of state can be rather stiff (in the $p - e$ plane) while being thermodynamically preferred with respect to the hadronic matter equation of state (in the $g - p$ plane). Interestingly, the two branches separate for values of mass of $\sim 1.6M_\odot$ at variance with other scenarios with separated branches, as e.g. the twin stars scenario, in which the new branch opens up at $\sim 2M_\odot$,[22]

In the two-families scenario the specific process of conversion of a HS into a QS has been extensively studied, see[23–25]: basically it is a combustion process which could be very fast (with time scales of the order of ms) due to hydrodynamical instabilities. The new stellar object has a larger radius with respect to the progenitor HS as studied in detail in Ref.[26]. In the twin-stars scenario instead, the formation of a hybrid star is triggered by a mechanical instability with respect to the gravitational collapse. It has to be shown that from a $2M_\odot$ star (where the twin branch starts)

one can form a much lighter ($M \sim 1.6 M_\odot$) and compact ($R \sim 10$ km) star (see[22]) preventing the collapse to a BH.

Finally, another difference between the two-families scenario and the twin stars scenario concerns the value of the speed of sound of quark matter: it can stay below or quite close to the conformal limit ($c_s^2 = 1/3$) in the former while it must be set to the causal limit ($c_s^2 = 1$) in the latter. In this case one should find out a physical mechanism that allows to match the pQCD results at asymptotic densities according to which c_s^2 must tend again to 1/3.
